Bilingual persons fluent in the original and target languages should perform the translation. A single person or committee can be used. Employing test translators who are familiar with the target culture, the construct being assessed, and principles of assessment minimizes item biases that may result from literal translations.

After the translation team has agreed on the best translation, the measure should be independently back-translated by additional person(s) into the original language. The back-translated version is then compared to the original for linguistic equivalence. If the two versions are not identical, the researcher works with the team to revise problematic items through a translation/back-translation process until agreement is reached about equivalence. This process, however, does not guarantee a good scale translation, as it often leads to literal translation at the cost of readability and naturalness of the translated version. To minimize this problem, an expert in linguistics should be consulted. Test instructions also need to go through the translation/back-translation process.

Once there is judgmental evidence of the equivalence of the two language versions, the translated scale needs to be pretested. One approach is administering both versions to bilingual persons. Item responses can then be compared using statistical methods. If item differences are discovered between versions, the translations are reviewed and changed

accordingly. Additionally, a small group of bilingual individuals can be employed to rate each item from both versions on a predetermined scale in regard to the similarity of meaning conveyed. Problematic items are then refined until satisfactory.

A small sample of participants speaking the target language can also provide verbal or written feedback about each item. The researcher may, for instance, randomly select scale items and ask probing questions (e.g., what do you mean by your response?). Responses considered unfitting an item are scrutinized and the translation changed. This method provides insight into how well the meaning of the original items has fared in the translation. Another method may involve respondents rating their perceptions about item clarity and appropriateness on a predetermined scale. Unclear items or items not fitting are changed. Finally a focus group approach can be used in which participants respond to the translated version and discuss with the researcher(s) the meaning they associated with the items and their perception about the clarity and cultural appropriateness of the items. Item wording can be changed based on participants' responses.

Along with the judgmental evidence just mentioned, statistical methods must be performed to verify equivalence and lack of bias. Cronbach's alpha, item-total scale correlations, and item means and variations provide information about instruments' psychometric properties. Significantly different reliability coefficients, for example, may indicate item or construct bias. Comparing these statistics across different language versions of an instrument offers preliminary data about equivalence.

Construct, conceptual, and measurement equivalence can also be measured at the scale level using factor analyses, multidimensional scaling, and cluster analysis. Scalar or full score equivalence is more difficult to establish than construct and measurement unit equivalence, and various biases (e.g., item and method bias) may threaten this level of equivalence. Item bias can be found by studying the distribution of item scores for all cultural groups. Item response theory, in which differential item functioning is examined, may be used for this purpose, as can analysis of variance (ANOVA), logistic regression, multiple-group standard error of the mean (SEM) invariance analyses, and multiple-group mean and covariance structures analysis. Last, factors contributing to method bias can be assessed and

statistically held constant when measuring constructs across cultures.

There are many examples of psychological measures translated from English to other languages. For instance, the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), including the adolescent form (MMPI-A), is available in nearly 20 languages. Multilingual versions of the Myers-Briggs Type Indicator, Strong Interest Inventory, California Psychological Inventory Sixteen Personality Factor Questionnaire (16 PF), Self-Directed Search, Millon Clinical Multiaxial Inventory-III, Revised NEO Personality Inventory (NEO PI-R), Hare Psychopathy Checklist-Revised, Beck Depression Inventory, State-Trait Anxiety Inventory, and Wechsler Intelligence tests are also available.

Often, information about availability and psychometric properties of translations and adaptations of tests can be accessed from the tests' developers or distributors. It is unclear, however, how translations of the measures mentioned above were performed and whether the tests were adapted for different cultural and linguistic contexts.

If one uses a test that has been translated into the language of a specific target population, but that has not been specifically developed and normed for that population, there is little to guarantee equivalence across such factors as item difficulty and relevance, cultural bias, comprehension/decoding, and validity within a differing cultural context. Beyond language, culture, and relevance, even the factor structure of a specific test cannot be assumed to exist in an adapted translation. This has, for instance, been observed in discussions regarding a 5- or 6-factor solution for the NEO PI-R in some specific cultural/linguistic adaptations. Psychologists worldwide, however, are striving to develop culturally sensitive and linguistically accurate translations of existing English version instruments. They are also developing measures for particular national and ethnic populations.

## TRAUMATIC BRAIN INJURY AND REHABILITATION

---

Traumatic brain injury (TBI) refers to damage to the brain caused by external physical force. It is the leading cause of long-term disability in young adults. Approximately 1.5 million Americans survive brain injuries each year, and an estimated 70,000 to 90,000 of these survivors are left with long-term impairments that interfere with their psychosocial adjustment and reintegration into the community. In the United States, an estimated five million individuals live with residual symptoms of TBI severe enough to interfere with

basic activities of daily living. TBI is most prevalent under age 24 and more than twice as common among men as among women.

### Causes and Mechanisms of Injury

TBI differs from other types of brain damage in its noncongenital and nondegenerative etiology and sudden occurrence during the course of normal health and development. Nearly half of all TBI occurs as a result of motor vehicle accidents; other common causes include falls, assault, and sporting accidents.

In open head injuries, damage to brain tissue tends to be localized at the site of injury. In contrast, closed head injuries tend to produce damage that is more diffuse. In incidents involving a blow to the head, the injury typically involves abrasions, lacerations, and contusions to the brain caused by impact with bony protrusions and rough membranes within the skull. A *coup-contrecoup injury* occurs when bruising occurs both at the site of impact and on the opposite side, as the brain bounces backwards in the skull.

In vehicular accidents, strong inertial forces can cause rotation of the brain within the skull. This twisting motion can strain fragile nerve fibers and blood vessels, and diffuse axonal shearing may result from the stretching and tearing of these microscopic structures. On the cellular level, disruptions in chemical connections between neurons and changes in basic metabolic processes may occur. The accumulation of molecules related to the cellular response to injury can create a toxic environment for surrounding neurons, leading to degeneration of these cells.

### Sequelae of Traumatic Brain Injury

Advances in emergency medicine and neurosurgery have led to increases in the TBI survival rate and a corresponding increase in the number of TBI survivors living with long-term adjustment problems. Typical problems include motor, perceptual, communication, and cognitive deficits.

Even with full physical and medical recovery, TBI survivors may experience persistent cognitive deficits in attention, concentration, memory, and higher-level executive functions involved in reasoning, planning, problem solving, emotional self-regulation, and judgment. In general, it is such cognitive and emotional changes, rather than any physical impairment per se, that contribute most to the disruption of life activities

for people with TBI. These impairments can compromise the individual's capacity to resume preinjury work and social roles, and the impact on quality of life can be profound. Long-term adjustment issues following TBI include unemployment, criminal behavior, loneliness, substance abuse, and loss of important social and family roles. Because the typical TBI survivor is a young adult with a normal life expectancy, cognitive deficits may lead to many years of social, vocational, and familial dysfunction, in which a person who may well be physically able is nonetheless dependent on others.

### Rehabilitation Methods

The Consensus Development Panel on Rehabilitation of Persons with Traumatic Brain Injury, convened in 1998 by the National Institutes of Health, recommended that rehabilitation be individualized, based on the person's residual strengths and limitations. Depending on severity of injury and the individual's needs, the rehabilitation team may include physiatrists, psychologists, speech and language pathologists, physical and occupational therapists, social workers, and vocational counselors. Rehabilitation may be provided on an inpatient, outpatient, or home-based basis or as part of a comprehensive day treatment program. Whatever the setting, counselors and psychologists face unique challenges in addressing the varied rehabilitation needs of people with TBI.

### Cognitive Rehabilitation

Cognitive rehabilitation is a systematic intervention designed to improve functional abilities and increase levels of independence following TBI. Prior to beginning cognitive rehabilitation, the individual typically completes a comprehensive neuropsychological evaluation to identify specific cognitive deficits, develop measurable goals, and guide treatment planning.

There are two general approaches to cognitive rehabilitation: restoration and compensation. The restoration approach is based on the premise that repetitive exercise can restore compromised cognitive abilities. Techniques include visual and auditory exercises, numerical tasks, computer-assisted exercises, feedback on performance, practice, and reinforcement. The compensation approach reinforces the individual's residual cognitive strengths while teaching strategies to circumvent (or compensate for) impaired cognitive abilities, with the goal of increasing independent

functioning. Compensatory strategies include the use of cues, written instructions, notes, calendars, date books, and electronic devices such as beepers and pagers. The individual is taught to minimize distractions, break complex tasks down into steps, and to self-monitor and self-regulate behavior. The two approaches are not mutually exclusive; both techniques are usually employed as necessary, depending upon the individual's needs.

### Psychological Issues and Interventions

Although there has been general support for the overall effectiveness of cognitive rehabilitation, evidence-based reviews have cited the need for more systematic study of treatment outcomes to determine practice guidelines. Despite obvious issues in impaired brain-behavior functions following TBI, accumulating data indicate that long-term adjustment is influenced by individual differences and by behavioral and social mechanisms to the extent that these factors account for more variance in any given outcome variable than diagnostic indicators of severity (particularly among persons with mild to moderate TBI). For example, persons with preinjury substance abuse histories are more likely to experience an array of personal and social problems after TBI. In general, individuals with a preinjury history of optimal personal, vocational, and social adjustment fare better than persons who do not. Current research indicates that persons who report more effective social problem-solving abilities following TBI are less distressed and less impaired than persons who report ineffective problem-solving styles, consistent with the extant literature concerning social problem-solving abilities among people in general.

Families are affected by TBI. Qualitative research has found that husbands of women with TBI report specific problems with their wives' loss of autonomy, mood swings, insecurities, overprotectiveness, reluctance to leave home, and change in lifestyle as particularly stressful. Wives of men with TBI report specific problems with husbands' personality changes, memory loss, lack of insight, lack of acceptance, reduction in financial resources, loss of emotional support, and feeling unable to meet children's needs. Family members who assume caregiver duties for a loved one with TBI have many concerns about interpersonal relationships, quality of life, and emotional commitments. Community-residing individuals with TBI report ongoing needs with improving memory, solving problems,

managing stress and emotional upsets, and in managing money and paying bills; these needs are particularly complicated by cognitive abilities, unemployment, and substance abuse.

Structured employment strategies appear to have the most promise in helping individuals with TBI return to work. Although other strategies exist, vocational rehabilitation efforts are hampered by decreasing financial support and the amount of time often required for successful training, placement, and work adjustment.

Cognitive-behavioral interventions have demonstrated some effectiveness for persons living with TBI. Problem-solving training has been associated with decreases in distress in psychoeducational group sessions with persons with TBI and in web-based programs for families living with TBI. It should be noted, however, there has been a long-standing interest in interpersonal group formats that could promote personal awareness and insight in a social context and could improve self-concept. Motivational interviewing has been espoused as an efficient and strategic method for addressing substance abuse issues among persons with TBI.

### Future Directions

The steady rate of growth in TBI in modern society constitutes a major healthcare and socioeconomic concern. Experts recently have witnessed an increase in TBI sustained by soldiers fighting in Afghanistan and Iraq, prompting Veterans Affairs hospitals to set up special TBI treatment and rehabilitation centers. As the number of TBI survivors continues to grow, millions, in the United States alone, now live with residual symptoms and long-term adjustment problems.

Researchers are optimistic that ongoing studies will lead to further advances in treatment and rehabilitation for people with TBI. Early research has indicated that cholinesterase inhibitors (currently used to treat early symptoms of Alzheimer's disease), may prove to be an effective treatment for TBI-related deficits in attention, concentration, and memory. Recent advances in genetics are also promising. For example, the apolipoprotein E4 (apoE-e4) genotype appears to increase the risk of poor outcome following TBI. Discoveries such as this may lead to the development of targeted medications or gene therapy for TBI treatment and rehabilitation.

Functional magnetic resonance imaging (fMRI) appears to be an important tool for understanding the neurobiological changes that occur in the brain during

cognitive rehabilitation. Preliminary research suggests that fMRI has the potential to identify changes that occur in functional neural networks during cognitive rehabilitation, thereby allowing for more targeted rehabilitative interventions. Finally, developments in stem cell research indicate potential benefits for people with TBI. Researchers have used adult human stem cells to grow functioning brain cells. Although this research is still in its infancy, stem cells from a patient's own bone marrow one day may be used to regrow and replace brain cells that have been damaged by TBI.

## TREATMENT COMPLIANCE

---

*Compliance* is defined as the degree to which patients' behaviors (e.g., attending follow-up appointments, engaging in preventive care, following recommended medical regimens) correspond with the professional medical advice prescribed. The terms *compliance* and

*adherence* are often used interchangeably; however, because compliance may carry a negative connotation, some prefer to use *adherence* to emphasize patients' active roles in healthcare management as opposed to the submissiveness suggested in the definition of *compliance*. This distinction in definition acknowledges that patients and providers can move away from the patriarchal model of health care, promotes patient autonomy, and takes into account evidence suggesting that those who adhere steadfastly to providers' instructions may not be the healthiest psychologically or physically. While the patient's active role is considered vital in committing to a treatment regimen, for the purposes of this overview, the term *compliance* is utilized to maintain consistency.

### Compliance Rates and Consequences of Noncompliance

When adults are diagnosed with chronic illnesses, they are often inundated with treatment options. Outright refusal to accept treatment is rare. Many who initially refuse later comply. As M. Robin DiMatteo found, on average, 75.2% of adults with chronic illnesses comply with prescribed treatments. While compliance rates for behavioral interventions (e.g., exercise regimens, smoking cessation) are consistently lower than this average (ranging from 40% to 75%), patients attend scheduled appointments at higher rates (up to 90%). Interestingly, despite the shift toward greater patient decision-making autonomy, across treatment regimens compliance rates have increased from 62.6% prior to 1980 to 76.3% thereafter. Among adults, highest compliance rates are documented for human immunodeficiency virus (HIV), arthritis, and gastrointestinal disorders. While an estimated 50% of children and adolescents with chronic illnesses fully comply with medical recommendations, rates fluctuate depending on the illness. Among children and adolescents with cancer, compliance ranges from 40% to 66%. Compliance for sickle cell disease ranges from 49% to 79%; approximately 66% of patients with cystic fibrosis and diabetes fully comply.

The consequences of noncompliance lie on a continuum ranging from relatively no direct patient risk to severely increased morbidity and mortality and an increased global threat of treatment-resistant diseases. Additionally, noncompliance results in medical resource waste and large-scale medical industry monetary losses exceeding \$100 billion per year.

## Assessing Compliance

### Self-Reports

Self-reports are commonly used to assess compliance. Examples include Likert scale questionnaires, handheld computers, and phone diaries. Although self-report measures are the simplest measures to use, report bias and recall precision issues often make results inaccurate. These inaccuracies can result in over-reporting, because patients may answer questionnaires consistently with what they believe promotes support and approval from providers. Underreporting is also concerning, with some research suggesting higher compliance when using objective measures as compared to self-reports. Despite challenges involved and acknowledgment that self-reports should be interpreted cautiously, because of their practicality, research supports using self-reports in clinical settings.

### Objective Measures

Pill counts, electronic bottles, and urine or blood serum levels are examples of objective measures of compliance. Although these measures can be expensive, many lessen opportunities for recall bias and human error via electronic tracking (e.g., counting number of puffs pressed on an inhaler). While they cannot guarantee that the patient completed the treatment, increased accuracy has been reported when using objective measures of compliance. Parents also report feeling more comfortable allowing their children to take control of treatment protocols when such devices are utilized.

### Collateral Reports

A third method of measuring compliance is through reports by family and healthcare providers. Although this method is rarely used, except with young children, it can be valuable to compare self-reports to reports from third parties.

## Correlates and Predictors of Compliance

### Adults

Compliance increases when patients believe treatments are necessary and important. Healthcare providers play a critical role in this process by helping patients weigh the risks and benefits while taking into

consideration social contexts and perceived barriers. Successful compliance also requires that an individual develops the motivation and self-efficacy required to confront a long-term stressor.

Decision-making autonomy enables the patient to feel more control and self-responsibility, perceive treatments as valuable, and achieve increased quality of life (QOL). Noncompliance risk factors include distress, perceived vulnerability, patient characteristics (e.g., demographics, social support), disease and treatment variables (e.g., complexity, side effects), contextual factors (e.g., provider-patient relationship, media exposure), and cognitive functioning (e.g., memory).

Examples of predictors of compliance are readily available. Online surveys find that most cancer patients and providers believe good communication promotes compliance; unfortunately, relatively few providers are comfortable discussing alternative or complementary therapies. Additionally, research among HIV/AIDS (acquired immune deficiency syndrome) patients suggests that poor social support, underestimation of illness severity, lack of factual information (e.g., not knowing the difference between HIV and AIDS), healthcare system distrust, side effects, and beliefs that medications are ineffective all decrease compliance.

Most research shows no major differences in compliance based on gender, marital status, country of birth, or primary language. Although conflicting findings exist with respect to the relationship between ethnicity and compliance across chronic illnesses, as compared to European Americans, fewer minority HIV-positive patients comply with treatment. Income-specific factors combined with high treatment costs also play a role in lower compliance rates, and many patients state that they must cut back on necessities like food or heat to pay for medications.

### **Children and Adolescents**

For children and adolescents, treatment compliance is influenced by numerous factors. In general, females are more compliant than males, and adolescents are less compliant than younger children. Among adolescents, researchers report that compliance may be related to adolescents' needs for independence combined with their willingness (or lack thereof) to accept the authority of healthcare providers. For example, research suggests that a cancer diagnosis coupled with cognitive impairments resulting from aggressive treatments

predicts poorer decision-making abilities, including higher incidences of high-risk behaviors (e.g., smoking, drug use). Self-esteem, cognitive and social functioning, lower socioeconomic status, lower parent education, feelings of invincibility, illness knowledge, perceived vulnerability, treatment complexity, emotional problems, and prevailing psychiatric illness also relate to compliance.

The overall strength of the parent-child relationship, including communication and familial organization, is crucial in successfully treating chronic illnesses. Parents must be prepared to complete a variety of tasks ranging from administering medications to assisting medical staff with invasive procedures. A lack of cooperation between parents and children and parenting inconsistency can result in added emotional distress, exacerbation of behavioral problems, and lowered compliance with medical protocols and other daily tasks. When anxious parents are overly restrictive, adolescents are less likely to follow prescribed treatments.

Predictors and correlates of compliance also vary by specific illness. For asthma patients, inadequate healthcare access, limited disease knowledge, inability to seek emergency care, conflicts with healthcare providers, family dysfunction, and poverty are all barriers. Among childhood cancer patients, noncompliance is more likely once maintenance therapy is introduced, because the most acute phase of treatment is administered by professionals, making noncompliance less probable. Children with sickle cell disease or juvenile rheumatoid arthritis are usually compliant with pain management interventions but may not comply with behavioral exercises and other treatments due to side effects and the amount of time required. In addition to time constraints, cystic fibrosis treatment can promote family conflict. Regardless of the specific illness, children and adolescents with chronic illness often report fears that compliance will interrupt typical life activities and change how they are perceived by peers.

## **Theory and Interventions Promoting Compliance**

### **Adults**

Several extant theories suggest factors fostering treatment compliance. Often these theories serve as foundations for interventions designed to increase behavioral compliance. Examples include the health

belief model by Marshall Becker and colleagues, which states that compliance is related to beliefs about illness severity and treatment regimen benefits as well as vulnerability perceptions. Irwin Rosenstock and colleagues' health benefits model add that patients will weigh the treatment costs and benefits before deciding whether to perform the recommended behaviors. Individuals who view themselves as more vulnerable or who view their illness as very serious are likely to exhibit greater compliance with health behaviors, thereby promoting positive outcomes. The role of self-efficacy, included in models such as Howard Leventhal's self-regulatory model of illness and Ronald Roger's protection motivation theory, is also salient in that patients displaying higher levels of confidence in their ability to complete treatment are more likely to succeed.

The way in which treatment is offered to patients can help promote compliance. Home health care increases compliance by increasing satisfaction with staff and decreasing treatment administration wait times. As compared to home health care, similar improvements in compliance are identified through educational interventions aimed at enhancing disease and treatment knowledge and through behavioral interventions, which assist with pain management and pill-taking procedures. Healthcare providers often also emphasize relaxation therapy and systematic desensitization to control side effects and promote compliance, although these approaches are less empirically supported.

A recent review of interventions targeting hypertension, schizophrenia and psychosis, asthma, depression, HIV, diabetes, rheumatoid arthritis, and epilepsy found that certain interventions work better for specific illnesses. Complex interventions involving care at the worksite, special pill containers, counseling sessions, phone calls, information pamphlets, workbooks, and support groups successfully increase compliance for hypertension and asthma. For patients with diabetes, self-care educational calls with a nurse work well, whereas individual counseling promotes compliance among HIV and epilepsy patients. Disease and drug informational pamphlets and teaching self-monitoring techniques also enhance compliance among those with epilepsy. Family therapy and individual educational sessions work best for individuals with schizophrenia and psychosis. Among patients with depression, informational pamphlets and drug counseling decrease depressive symptoms, decrease relapses, and increase compliance. When patients are depressed and have a

chronic illness, behavioral therapies have successfully extinguished depressive symptomology and increased reinforcement of healthy behaviors, including treatment compliance.

### Children and Adolescents

As Dennis Drotar argued, when developing interventions promoting compliance among children and adolescents, special considerations are required. Specifically, it is necessary to include the entire family in facilitating change. A well-developed intervention sets its own unique objectives, identifies risk factors, and works to enhance resilience factors and competencies. The underlying theory must be identifiable. If an intervention is successful but the theory cannot be identified, it will be nearly impossible to identify the mechanism of change. Many competing theories involving the entire family have been utilized to explain barriers to compliance. Examples include models that aim to separate risk factors, such as psychological stressors and functional independence, from resilience factors, such as dispositional traits and coping ability (James Varni and Jan Wallander's disability, stress, and coping model) and models focusing on the family's level of stress and burden as predictors of aversive outcomes (Reuben Hill's ABCX family crisis model).

Three primary strategies exist in intervening to encourage compliance. Educational interventions focus on teaching families about the child's disease, treatment requirements, and self-management proficiencies. Organizational interventions work to modify the physical healthcare setting to make it more welcoming and accommodating. This may include decreasing wait times and increasing the frequency of follow-up care. Behavioral interventions include stimulus control techniques that utilize visual cues and written reminders, self-control techniques (i.e., self-monitoring medication use), and reinforcement control techniques (i.e., token economies).

Treatment plans and interventions must be determined with a great deal of individualization based on the needs of each child. For example, among children with asthma, compliance is often problematic, because the disease can be unpredictable with long symptom-free periods. Plans for preventive care, avoidance of triggers, and promotion of medication compliance are all necessary and are enhanced through simple behavioral interventions such as teaching how and when to use medications, goal-setting techniques, and

self-management skill development. Healthcare providers must also be taught to provide developmentally appropriate written or pictorial explanations of their recommendations. Across varying types of chronic illnesses, healthcare providers who are willing to spend extra time communicating, supporting, and supervising care are more likely to achieve better compliance.

### Future Research Considerations

For interventions to be effective, researchers and healthcare providers must first understand the predictors of successful compliance and factors encouraging noncompliance, including the patient's emotional status, culture, and belief system. Healthcare providers often play a primary role in influencing a patient's belief systems. It is commonly understood that patients must trust healthcare providers before complying with treatment; however, research must work to specify precisely how variables such as rapport, mutual respect, empathy, and humanism impact compliance. The examination of what types of information patients can absorb at certain stages of their diagnoses and treatments and how practitioners engage patients in the decision-making process are also pertinent. There are many other questions that remain unanswered as well. Several of these questions center on patient beliefs such as determining the role of prognosis, illness severity, denial, guilt, and alternative or homeopathic therapies on compliance. Practical matters like daily chronic stressors, motivation, peer influences, emotional distress, family dysfunction, and family cohesiveness also require further investigation.

## TYLER, LEONA E. (1906–1993)

---

Leona Elizabeth Tyler was born in Chetek, Wisconsin, on May 10, 1906; she died at the age of 86 in Eugene, Oregon, on April 23, 1993. By her own admission, an established field of counseling psychology did not exist when she began her full-time graduate training at the University of Minnesota in 1938, but Tyler made a significant contribution to the definition and evolution of the discipline throughout her career. She founded a university counseling service; wrote an authoritative counseling text, *The Work of the Counselor*; served as president of the American Psychological Association's (APA's) Division of Counseling Psychology (1959–1960); and was ultimately elected president of the APA (1972–1973). In fact, Tyler's contributions to the counseling field were so significant that counseling psychology's most prestigious award is named in her honor. Her professional and scholarly work was not confined, however, to counseling. Her career at the University of Oregon spanned more than three decades and included appointments as a professor in the psychology department and dean of the graduate college. A prolific author, she published more than 50 journal articles and penned books on diverse topics, including individual differences, developmental psychology, clinical psychology, psychological testing, intelligence, and creative thinking.

### Education and Training

Although born in Wisconsin, Tyler lived most of her early years in Minnesota in the area of the Mesabi Iron Range. Her parents had not earned college degrees, but she spent 2 years at Virginia Junior College and ultimately graduated from the University of Minnesota at age 19 with a degree in English. She then began a career as a junior high school teacher. In her own writings, Tyler noted that she enjoyed teaching but found maintaining classroom discipline stressful. After more than a decade, she considered making a career change and becoming a counselor, which led her to enroll in a summer class at the University of Minnesota in 1937. Her professor for that class, Donald G. Paterson, recognized her talent, convinced her to pursue full-time graduate studies in psychology, and helped her to obtain a graduate assistantship.

The psychology department in Minnesota did not provide specialty training at that time, but Tyler noted

it did present significant opportunities for training in counseling. She completed a practicum at the University Testing Center and learned about assessment techniques, particularly interest assessment, and practiced educational and career guidance. In addition to her counseling experiences, Tyler's comprehensive graduate training included a minor in statistics and interactions with noted professionals, such as developmental psychologist Florence Goodenough. Tyler became well versed in general psychology as well as specialized topics, which prepared her to teach courses from counseling and guidance to social psychology and research methods. She ultimately taught in all of these domains during her academic career at the University of Oregon, which began with her appointment as an instructor in the psychology department in 1940.

### Early Years at the University of Oregon

When Tyler took the position in Oregon, she became the only woman in its small psychology department. These early years were both professionally productive and personally satisfying to Tyler, who would later describe them as some of her happiest. She enjoyed the intellectual stimulation that came from working with other faculty members and graduate students, and she considered herself quite successful at this career stage.

Always one to bridge the gap between science and practice, Tyler stayed active as a counselor while maintaining her scholarly and teaching activities. Although there were no counseling facilities at the University of Oregon, Tyler quickly started a counseling service to provide occupational assessment and guidance to students. However, as World War II came to an end, her focus shifted to providing counseling to veterans as they returned home from the war. Through the years, this counseling service developed into the official University Counseling Center, and she continued to work there part-time until 1965.

In addition to her success as a counselor and teacher, Tyler also published her first book, *The Psychology of Human Differences*, in 1947. The text, which would appear in three editions, addressed issues related to measuring and understanding individual differences in a wide range of constructs, including intelligence, personality, and perception. Tyler also discussed group differences in various domains based on sex, race or ethnicity, and social class.

## Establishment as a Scholar and Professional

Although satisfied with her career progress at the time, Tyler acknowledged later that her advancement was most likely slowed by sexist attitudes held by many in the field. Her scholarly productivity continued, however, and she received recognition for her work during the 1950s. She identified her 1951 sabbatical in London as a pivotal time in her career for several reasons. First, she enjoyed scholarly success and had the opportunity to focus on data analysis and writing. Her time in London also brought her into contact with noted personality theorist Hans Eysenck. As important as her professional endeavors, her personal experiences in London broadened her cultural horizons and exerted a key influence. In fact, it was there that she first encountered existentialism, which she credited for impacting much of her later work.

Tyler also started her second book, *The Work of the Counselor*, during her sabbatical year. Published in 1953, this textbook for counselors in training became profoundly influential. It was used in training programs across the globe, spawned two subsequent editions, and established her as an expert in the field. These texts integrated research and practice and covered everything from conducting the first interview to evaluating the effects of counseling.

Following the success of her second book, Tyler assumed a number of professional leadership roles. She became the president of the Oregon Psychological Association in 1956, the Western Psychological Association in 1957, and the APA's Division of Counseling Psychology in 1959. Her allegiance to counseling did not keep her from branching into other disciplines. She collaborated on a developmental psychology text with Florence Goodenough, a graduate school mentor, and wrote a clinical psychology textbook with colleague Norman Sundberg.

Tyler is best known for her books and her work in professional leadership roles, but she also enjoyed success during this time publishing original research. Her work often involved interest measurement in children and adolescents. She also developed a new theoretical framework for individuality. She used her 1958 Western Psychological Association presidential address to present her perspective that a person's uniqueness results from making choices among available possibilities and providing a mental organization

to those choices. She viewed these ideas as an important complement to existing approaches to trait measurement, and they influenced her development of the choice pattern technique as a career counseling assessment tool.

## Late Career and Professional Legacy

Already a textbook author and authority in counseling, clinical, and developmental psychology, Tyler added psychological testing to that list with the publication of *Tests and Measurements* in 1963. Her scholarly work during the 1960s and 1970s also included several collaborative cross-cultural studies, including an examination of choice patterns in teens from India, the Netherlands, and the United States.

Tyler's final appointment at the University of Oregon was as the first female dean of the graduate college, a position she held from 1965 until she reached mandatory retirement age in 1971. Even after official retirement, she continued with an active professional life. She served as president of the American Psychological Association from 1972 to 1973, and she worked on various boards for the organization into the 1980s. She also wrote with consistency and frequency, authoring books on individuality and creative thinking.

Tyler's legacy is significant. She influenced the field of psychology as a whole through substantial empirical research, important books in several fields, a record of mentoring significant numbers of graduate students, and work within APA governance at its highest levels. Her mark on the counseling profession was profound. In fact, she helped to define the counseling field and its professional training with her text, research, counseling center work, and service to the Division of Counseling Psychology. Beginning with *The Work of the Counselor* in the 1950s and continuing into the 1990s, Tyler advocated for counseling as an activity and profession that could be helpful to any person by facilitating self-understanding, development, and making the choices she saw as so central to individuality.

## UNIVERSITY COUNSELING CENTERS

---

Universities and colleges have provided counseling services to students for over 80 years. Early on, counseling was often conducted by psychiatrists who worked in student health services. In the 1930s, there was movement for counseling to be conducted by counselors and psychologists who viewed students' problems from a normative developmental model and were trained in student personnel programs or psychology departments. Since then, university counseling centers have emerged as a specialty area within counseling psychology that calls for psychologists to provide counseling for students with both developmental and adjustment-related concerns as well as more serious pathology. In addition to clinical services, university counseling center psychologists provide outreach and consultation to the larger university campus communities, provide training for graduate practicum counselors and predoctoral interns in counseling and clinical psychology and social work programs, attend to staff development within their agencies, conduct research applicable to college student populations and therapeutic practices, and develop administrative policies and programs that help to inform and guide the counseling psychology field. This entry begins with a brief historical overview of university counseling centers and then describes the current six counseling center functions as originally outlined by Stone and Archer, as well as multicultural and diversity factors that are involved throughout these functions.

### Historical Overview

University counseling centers (UCCs) have transformed greatly since their formative years, and these transformations have often mirrored emerging mental health needs and personal growth concerns of the larger culture. During the 1940s, the role of clinical counselor was developed as an individual who could work with the specialized needs of college students. Following World War II, counselors were called on to provide vocational guidance services for returning veterans. During the 1950s through 1970s, outreach and consultation services were added to the work of university counseling centers, causing counselors to view the entire university as their "client" rather than just individual college students. In the 1980s, UCCs were faced with increasing numbers of students with serious mental health concerns (e.g., sexual violence, eating disorders, suicide) and with the need for campus education and consultation to address these issues.

From the 1990s through the beginning of the 21st century, university counseling centers have continued to work with students with serious mental health concerns, but during this time financial constraints have necessitated decreases in service provision, such as limiting counseling sessions. This limitation of counseling sessions is similar to the current therapeutic practice allowances of many third party payment plans, which has contributed to an increase in a medical model approach. This includes a reliance on diagnosis (e.g., the use of the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition: DSM-IV*), psychotropic medications, and standard of

care approaches that involve the professional practice of reasonable and prudent mental health professionals who have specialized training in the diagnosis and treatment of clinical issues.

In many ways, the field has seen a full circle that also embraces many of the emerging perspectives of the last 80 years, from counseling provided by psychiatrists from a medical model during the 1920s to counselors providing mental health treatment from a developmental and adjustment-oriented perspective and back to current practices of considering both developmental and medical models when working a college student population.

### University Counseling Center Functions

University counseling centers have moved away from their early, primary function of only providing mental health care for students to one that now also provides educational programming to and consultation with the larger campus community, conducts preventive and remedial interventions, and does so in ways that adhere to innovative counseling, consultation, and educative practices. Over thirty years ago, Morrill, Oetting, and Hurst developed the cube model to describe the varying dimensions of counselor functioning within the UCC setting. This cube included the *targets* of interventions (individual, primary group, associational group, and institution or community), the *purpose* of interventions (remediation, prevention, or development), and the *method* of intervention (direct services, consultation and training, and media).

More than 20 years later, Pace, Stamler, Yarris, and June further developed the cube model to one that was “rounded out” to describe the evolution of UCC functioning that better addressed the interdependent university community. This newer model addressed the demands on UCCs to interact with various university and community agencies in more complex ways managing student development and counseling needs. Rather than viewing UCCs as an independent entity within the university and one that considered the targets, purpose, and methods of intervention as independent from one another, the rounded out model embraces the interdependence, collaboration, and flexibility necessary to improve the developmental and clinical needs of the student population.

University counseling centers today have evolved into multifaceted agencies that are well integrated into

the larger university system and provide a variety of functions. Stone and Archer randomly surveyed UCC directors and training directors and, from their findings, developed six different counseling center functions: clinical services, outreach and consultation services, training, staff development, research, and administration. While not all UCCs address these functions (e.g., not all UCCs offer training to graduate students in counseling and clinical psychology and social work), most UCCs’ functioning includes many of these areas. As a follow-up to these findings, Guinness and Ness surveyed UCC directors to assess whether there had been, in recent years, significant changes in these areas that were central to UCC functioning. They determined that more than half of the directors surveyed indicated positive changes in all six areas, suggesting that these functions remain essential to UCCs and that ongoing assessment can help identify areas of improvement.

### Clinical Services

Research suggests that UCC psychologists believe that students’ presenting problems in counseling are more severe than in previous years, leading one author to suggest that UCCs are looking more like community clinics. These problems include drug and alcohol abuse, eating disorders, sexual violence and other trauma-related concerns, self-mutilation, severe mood disorders, and suicide. There are varying reasons as to why students may be presenting with more pathology than in past years.

Levine and Cureton suggest that in today’s college culture, students are less prepared academically, and they seek ways to escape from their overwhelming distress about their current concerns and uncertain future. Avoiding distress may contribute to depressive and anxiety disorders, and some escape activities (e.g., alcohol abuse) are detrimental to positive mental health. Kadison and DiGeronimo, in addressing this idea of students’ increasingly experiencing feeling overwhelmed by life, also note that some psychological concerns are likely to first manifest during young adulthood (such as bipolar disorders and eating disorders). Third, new and available psychotropic medications enable students who might not have previously been able to attend college to do so today. Fourth, college students today report valuing counseling and agree that they would seek counseling if the need were to arise. They also expect that counseling should be available at universities. Finally, the popular media

have noted the rise of “helicopter parents,” or parents that pay extremely close attention to their child attending college. Such parents may be more able than parents in the past to pick up on emotional difficulties of their college student children and are likely to refer them to counseling.

At the same time that UCCs are asked to address the increased severity of students’ mental health concerns, because of financial limitations, UCCs are not increasing the number of staff to provide counseling for students. Additionally, due to dwindling resources, UCCs have increasingly instituted session limits on counseling. The challenge becomes how to address college students’ clinical severity within a brief psychotherapy model and with fewer staff than in the past. One suggestion is that UCC psychologists use empirical research and standard of care treatment options to inform them on how to best provide counseling to students with various, complex presenting difficulties in a session-limited counseling model. Another suggestion is to use outreach and consultation efforts as a primary prevention targeted to all students and asking those in close contact with students (e.g., residence hall personnel) to help identify those who are in distress. Doing so may lead these students to start counseling before they are in crisis, thus decreasing the need for numbers of counseling sessions that may be greater than overall session limits. An additional option is to employ more testing and assessments with complex cases to better diagnose and provide treatment recommendations in a timely manner. A final suggestion is for UCCs to annually assess the chronicity and severity of students’ presenting difficulties to alert university and college administration about the need for additional resources.

### ***Outreach and Consultation***

Outreach, consultation, and other related services have become an increasingly important component of university counseling centers. Stone and Archer defined *outreach* as an “organized program, workshop, media effort, class, or systemic attempt to provide psychological education” and *consultation* as an “activity where a staff member provides advice and assistance based on psychological principles to a clearly understood client (group, office, department, club, and others)” (p. 557).

Providing outreach and consultation allows UCCs to diversify their methods of service delivery, meet the

needs of the ever-changing college student population, and provide educative and supportive efforts to students and university personnel outside of the counseling office.

### **Outreach**

Organized programming and workshops can serve the needs of students who traditionally do not access counseling services, such as men and students of color. Such programming may demystify and destigmatize counseling, educate university personnel or friends of students about how to encourage those in need to seek counseling services, and inform students about ways to prevent problems during particularly stressful times (e.g., avoiding alcohol abuse during the first week living in the residence halls). Outreach efforts may also encourage students to seek counseling when they struggle with a concern but, because of varying stages of readiness to change, may not otherwise do so.

Outreach programming may include addressing less serious concerns, such as decreasing test anxiety, reducing general stress, improving time management, and dealing with long-distance relationships as well as addressing more serious concerns such as sexual assault prevention, drug and alcohol abuse prevention, body image concerns, identifying the warning signs of depression and suicide, and dealing with hate crimes on campus. Innovative methods might include using peer presenters when appropriate, online workshops, and focus groups and post presentation surveys to help improve future attendance and delivery methods.

One particularly useful way to identify the outreach presentations often used at UCCs as well as assistance in developing new programs is to visit Workshop Central at the online Counseling Center Village at the University of Buffalo. Outreach outlines and handouts, workshop design strategies, and program evaluation paperwork that have been used successfully at other universities and colleges are readily available on this site.

### **Consultation**

The most effective consultation methods involve multifaceted services that focus on student advocacy and support as well as faculty and staff training. Quite often, distressed students come initially to the attention of faculty members, other university personnel, friends, or parents who do not know how to approach students

about their concerns or where to refer them for help. Additionally, issues may arise with students that are not necessarily directly counseling related but may be distressful within a campus community. As examples, this may include how to deal with offensive student remarks directed at international students in a classroom or how to address a Greek residence when a fraternity member has been called to military service and whose fraternity brothers have differing views on war.

A variety of consultation models exist to help UCC psychologists provide advice and assistance to a client, whether the client is a faculty member in a classroom or a Greek advisor living in a fraternity house. As an example, in process consultation, a UCC psychologist acts as a facilitator who targets the interactions of group members, helps develop goals, helps the group come up with viable solutions to reach these goals, and assists the group in making the changes necessary to reach their goals. Process consultation has been further developed to address the unique needs within the university setting and help UCC psychologists more effectively provide assistance to campus departments, agencies, and groups.

### ***Graduate Training***

Training models for graduate counseling psychology programs started in the late 1940s, and, in 1979, the American Psychological Association (APA) developed accreditation standards that required a predoctoral internship to obtain a doctoral degree in psychology. The Association of Counseling Center Training Agencies (ACCTA) was founded in 1978 to represent the interests of UCC training sites at national and state levels, provide liaisons with other groups involved in the training and credentialing of counseling psychologists, and serve as a forum for issues related to training predoctoral interns and practicum counselors. Currently, 150 UCC training directors are members of ACCTA.

In 2007, 3,430 doctoral students sought predoctoral internships at 640 sites and competed for 2,884 positions accredited by the Association of Psychology Postdoctoral and Internship Centers. Many of those who obtained an internship will be doing so at a UCC. University counseling centers provide more counseling and clinical predoctoral internship positions than other training sites. In addition to providing predoctoral internship training, UCCs also provide practicum training for doctoral students. Given the

increased competitiveness of internship applicants (in 2007, 842 doctoral students were not matched at internship sites) and to strengthen their chances of obtaining an internship, students are completing more practicum hours than in past years. Unfortunately, despite the amount of predoctoral interns and practicum counselors who receive their training at UCCs, there are some concerns that academic training programs may not adequately prepare students to provide a wide range of services necessary to work in a university setting.

University counseling center psychologists need to be trained to work with developmental issues unique to college students as well to diagnose and treat more serious concerns. Ethical standards within counseling and clinical psychology are moving toward the adoption of uniform standards of care within the field, and UCC psychologists are increasingly expected to use the standards competently. Counseling session limits are commonplace in UCCs, and graduate programs need to train students to work within briefer therapy models. Additionally, UCC psychologists need to be well versed in assessing risk management, providing crisis intervention and group work, and addressing public health issues relevant to a college population. Training should also include competence in clinical and learning disability testing as well as drug and alcohol abuse assessment and treatment. Finally, additional competencies necessary for training include program development, outreach programming, consultation, career development, and clinical supervision and training.

All of these specialized clinical and other mental health services need to be conducted in a multiculturally competent manner. Graduate programs must provide training for future psychologists to work with multicultural and diverse communities. As the United States is becoming an increasingly diverse and multicultural society, so are student populations. As a result, multiculturally attuned UCCs are imperative in order to work effectively with the ever-changing university community. Necessary multicultural competencies for a graduate student to work in UCCs include a counselor's awareness of her or his own assumptions, values, and biases; understanding of the worldview of culturally different clients; and the development of appropriate intervention strategies and techniques that take into account the clients' beliefs, attitudes, knowledge, and skills.

In response to the call for graduate training in diversity and multiculturalism, in 2000, the APA adopted

the *Guidelines for Psychotherapy With Lesbian, Gay, and Bisexual Clients*; in 2002, the APA adopted the *Guidelines on Multicultural Education, Training, Research, Practice, and Organizational Change for Psychologists*; and in 2007, the APA council approved the *Guidelines for Psychological Practice With Women and Girls*. These policies serve as aspirational documents for psychologists to integrate and infuse multicultural and sexual diversity issues and issues pertinent to the treatment of women and girls in all aspects of the practice of psychology. The adaptation of these policies in the UCC setting is a step in addressing the specific needs of increasingly multicultural and diverse student populations.

### **Staff Development**

In order to address changes in student populations and presenting difficulties of students who seek counseling, it is important for UCC psychologists to keep up with changes in the field of professional psychology. University counseling centers must assess the demands unique to their student populations as well as changes in the broader field and modify their practices to meet these new demands. UCCs need to actively pursue well-planned programs for staff development. This may include continual improvement in clinical assessment skills, risk management and crisis interventions, and brief and solution-focused psychotherapies. In the past, UCCs have often hired psychologists who are generalists and can work with a variety of client difficulties. In response to the increased chronicity and severity of student presenting concerns and the need to respond more effectively to populations that may be underrepresented (e.g., students of color), UCCs may want to encourage staff members to seek specialization in certain clinical areas or with particular populations. Finally, it is critical that all UCC psychologists continually develop their diversity and multicultural competencies.

Additional to addressing the need for ongoing staff development to improve clinical services, UCC psychologists also need to attend to their own career satisfaction. University counseling centers are a popular career choice for new doctorates in professional psychology, and most new psychologists are satisfied with most aspects of their first professional positions. Despite this overall initial satisfaction, Parham noted three central career issues for UCC psychologists 7 to 10 years into their careers, which may provide reasons for

psychologists to search elsewhere for professional positions. These include professional burnout, difficulty with finding time for personal and other professional activities, and a shift in age relative to the student population. There are a number of ways UCC administrations can address these career concerns. Developing and maintaining a supportive and positive UCC culture that provides ongoing encouragement for staff career and professional development and opportunities for leadership and administrative skill development, encouraging staff to develop programs in their areas of interest and to participate in professional organizations and research, and keeping staff involved in the planning and operation of the UCC and to confront job satisfaction issues (such as burnout) from a developmental perspective are ways to help staff improve career fulfillment.

### **Research**

The International Association of Counseling Services (IACS) identified conducting research as a core role and function of UCCs. According to the IACS standards, research efforts include the evaluation of clinical services, program assessment, and scholarly study. Even though IACS notes the importance of conducting ongoing research, especially to determine the effectiveness and improve the quality of services, most UCCs do not do so in any systemic manner. One reason for the lack of research activity includes a lack of time and resources. UCCs' missions are likely to focus more on clinical and ancillary service delivery than on conducting research. With dwindling resources to hire more psychologists to address increasing clinical need, research often falls as a distant priority to providing counseling and outreach services.

Another reason may be a move from some psychologists viewing themselves as scientist-practitioners to identifying as practitioner-scholars. That is, with more programs increasingly emphasizing the practice of counseling over developing research skills, psychologists who choose to work at UCCs may be less likely to value conducting research.

A final reason for the lack of research involvement is that UCC psychologists may believe that research only entails conducting carefully controlled experimental studies that are published in scholarly, peer-reviewed journals. To counter this belief, Boyd, Roberts, and Cook proposed a UCC research program: conducting research to identify demands for services, understand and assess changes in student

characteristics, recognize counseling effective outcomes, and provide a data resource for the campus housed within the UCC.

### Administration

UCCs may be organized in one of six ways: as a center that provides educational services; a counseling center for students and employees; a health-services counseling center; a privately contracted counseling service; a center that provides consultation for organizational and community development; and a center that provides comprehensive counseling services and community development. The way in which a UCC is organized is usually based upon the size, location, funding pattern, or philosophy of the university or college. While one organizational model is not inherently better than another, some have suggested that for the survival of UCCs, it is imperative to align UCC goals with those of the larger institution.

To this end, it may be that the preferred UCC model is one that provides multiculturally sensitive, comprehensive counseling services and community development. This type of UCC is one that offers the following: comprehensive counseling services (individual, couples, career, and group counseling); specialized counseling for more serious problems (e.g., eating disorders, alcohol and drug abuse, sexual violence); crisis services (including after-hours care); outreach and consultation services for student groups, staff, and faculty; training and supervision of graduate practicum counselors and predoctoral interns; research that involves service accountability; psychiatric care; and community development work that involves and includes many different university departments and services and local community agencies.

### Future Directions

Counseling for university and college students has changed and evolved over the course of 80 years. The current mission of university counseling centers is to be full-service agencies that provide counseling for individuals, couples, and groups with developmentally related concerns as well as more complex and serious problems. Additionally, they provide outreach and consultation services, provide graduate training and supervision for counseling and clinical doctoral students and interns, attend to staff development within their agencies, conduct research and program evaluation,

and help to develop administrative models and policies relevant to the field of counseling psychology. Future efforts will continue to focus on ways to provide exceptional counseling services to students in the face of dwindling resources and ways that university counseling center psychologists can conduct research to improve their efficiency while also attending to the demands of counseling and ancillary services.

## VASQUEZ, MELBA J. T. (1951– )

---

The professional accomplishments of Melba J. T. Vasquez are innumerable. Clinical practice, leadership, advocacy, education, and research are among the areas in which she has excelled. Vasquez's work has positioned her not only as a pioneer within the field of psychology but also as a true example of determination and perseverance. Having grown up and later come of age around a climate of intense racial and political unrest, Vasquez encountered challenges that later became empowering experiences that influenced and continue to influence her work in many ways.

Vasquez is the first of seven children born to her parents and grew up in San Marcos, a small town in central Texas. In her writings, she has described enjoying considerable attention from her parents and extended family members, feeling safe in her community even though it was socially segregated, and not realizing her family was poor until she reached the age of 6. As she was growing up, Vasquez's parents were very active in their community, participating in political rallies, voter registration projects, and fundraisers for Latina/o students. She noted her mother emphasized the significance of education, justice, and behaving as if they were deserving even if others did not seem to agree with such message.

Vasquez recalls feeling unsafe for the first time when she began elementary school and realized there was not a single teacher or administrator of color. Though she was very young and unable to put words to her experience, Vasquez notes she felt sadness and the loss of positive regard at a personal and group

level due to seeing that children of a similar background were treated negatively. She soon learned that being a good student was the best way to get positive regard and a feeling of safety back.

Throughout her school years, Vasquez encountered difficult experiences such as hearing from her second-grade boyfriend that she could not be his girlfriend due to her ethnicity, finding out that the boys in the homecoming court were not willing to escort her for the same reason, and discovering that fellow high school cheerleaders excluded her from social gatherings.

The meaning of sisterhood began to emerge during Vasquez's elementary school years. The importance of allies became easier to elucidate after an African American young girl defiantly interceded for Vasquez and her sister when they were being bullied by a White boy. In high school, Vasquez was elected to leadership positions by students of various ethnic backgrounds who had formed networks to gain representation. She excelled despite the painful challenges she encountered.

Vasquez received a bachelor's degree in English and political science with a teaching certification from Southwest Texas State University. While in college, she encountered other salient life experiences. For example, she realized that individuals of White ethnic background can also be allies and found a mentor in Colleen Conoley, a woman who encouraged her to pursue a doctorate in counseling psychology.

In college, Vasquez represented one of her student organizations in a beauty pageant. She was chosen as a semifinalist and later evoked the astonishment of friends and advisors when she declined to participate in another beauty contest. She could not yet articulate her

disapproval of patriarchy's objectification of women, but this experience awakened the feminist in her.

Vasquez notes that Conoley suggested a doctoral degree in counseling psychology would provide more extensive options for her. At that point in time, Vasquez had been teaching for about a year and was engaged in part-time graduate work toward a master's degree in school counseling. Though not fully grasping what those options would entail, Vasquez was intrigued by the study of human behavior and was interested in achievement, as she suspected racism, sexism, and lack of opportunity were intricately related. Motivated by the desire to dissipate some of her confusion via the acquisition and later the creation of knowledge, Vasquez embarked on a path toward doctoral education at the University of Texas (UT) at Austin. She completed her doctoral degree in counseling psychology in 1978. She encountered discouraging situations with some professors, and at times questioned whether she belonged but was determined to prove that she did, in fact, belong. Vasquez received great support and mentorship from other professors, especially those who were part of her committee. In addition, being one of the first recipients of the American Psychological Association's (APA) minority fellowship became an additional incentive to continue her studies.

Vasquez recognizes that affirmative action made it possible for her to be a psychologist and views this initiative as a central strategy to promote social justice. She also poses that affirmative action may have been a contributing factor to her subsequent job attainments at Colorado State University's and UT at Austin's counseling centers, where she served as director of training. Vasquez has been successfully dedicated to full-time independent practice for over 15 years and provides consultation and training for organizations as well as forensic consultation in addition to individual and group therapy. She has published extensively on a wide variety of topics, including psychology of women, feminism, professional ethics, ethnic minority psychology, training and supervision, and multicultural competence.

Vasquez's dynamism and leadership are present across various divisions of the APA. She is a fellow of divisions 1, 17, 35, 42, 45, and 49 and is a member of divisions 9, 31, 44, and 56. She has presided over APA's divisions 17 and 35 and the Texas Psychological Association, she is the treasurer of division 56, and she is the first Latina/o to be a member of APA's Board of Directors in the 117-year history of APA. She has

chaired APA's Board of Professional Affairs, the Board for Professional Advancement, the Ad Hoc Council Committee on the Revision of Standards for Educational and Psychological Testing, the Ad Hoc Committee on Legal and Ethical Issues in the Treatment of Interpersonal Violence, the Task Force on Communication with Minority Constituents, and the Board of Ethnic Minority Affairs. More recently she has been part of APA's Council of Representatives Task Force on the World Conference Against Racism's Report and of APA President Ron Levant's Task Force on Enhancing Diversity.

Vasquez's influence has also been present in conference planning endeavors. She was part of the steering committee for the Competencies Conference 2002: Future Directions in Education and Credentialing in Professional Psychology, which was hosted by the Association of Psychology Postdoctoral and Internship Centers. In 1999, she joined forces with other influential and visionary psychologists to establish and organize the annual National Multicultural Conference and Summit, which highlights research and practice that centers on multicultural psychology.

Additional affiliations include Vasquez's involvement in the foundation of the National Latina/o Psychological Association and in the Texas Psychological Association, an organization which was recently under her direction. She was recently associated with the Southwest Texas Foundation Development Board and with the Austin Women's Psychotherapy Project, of which she is a cofounder.

Through her parents' activism, Vasquez learned that the pain and anger resulting from disenfranchisement were to be directed by way of proactive involvement. This lesson seems to be palpable in her endeavors and her commitment to the advancement of psychology. Her efforts have been celebrated by multiple awards, recently including receiving APA's Award for Distinguished Professional Contributions to Independent or Institutional Practice in the Private Sector, being named Woman of the Year by Division 17's Section for the Advancement of Women, being awarded an honorary doctorate degree by Phillips Graduate Institute, and receiving APA's James M. Jones Lifetime Achievement Award.

Vasquez is a pioneer, an excellent role model who, regardless of her current status as a prominent psychologist, continues to be loyal to her principles and vision of what psychology as a profession should provide for Latinos/as, women, and other marginalized

groups in society. Vasquez also leads by example as she promotes the importance of coalition building and the necessity to build bridges and resolve conflict between communities. Vasquez's indefatigable labor continues via multifarious venues. She is a *mujer* of character and her work as a therapist, researcher, lecturer, advocate, and leader is *sui generis*.

perspectives, and these are the moral principles that are commonly accepted. So, for example, many ethical codes rest on the following principles: respect for autonomy (agreeing that another person has the right to think and choose as he or she wishes), nonmaleficence (not harming another person), beneficence (taking positive actions toward another person), justice (equality in the distribution of benefits and tasks), fidelity (meeting one's responsibilities in a relationship based on trust and commitment), and veracity (truthfulness and integrity). The difficulty with any set of ethics based on principles is that principles can "collide" in an ethical dilemma. So, for example, in informing another person that one's client wishes to do harm to that person, a therapist is elevating the principle of nonmaleficence over that of autonomy.

Virtue ethics is a contrasting perspective on ethics. Virtue ethics, expanded in large part by Naomi Meara, is the belief that a person's motivation, character, morality, and ideals are more likely to lead to ethical actions, or the lack thereof, than principles or regulations. Virtue ethics calls individuals to aspire to personal standards of ethics and morality that rise above those of *de minimis* actions and represent aspirations or ideals that are striven for. People who are "virtuous" in this sense of the word share common characteristics, according to Meara, Lyle Schmidt, and Jeanne Day. They are "motivated to do what is good, possess vision and discernment, realize the role of affect or emotion in assessing or judging proper conduct, have a high degree of self-understanding, and are connected with and understand the importance of community in moral development and decision making" (pp. 28–29).

One difficulty with this approach is that there is a range of virtues, just as there is a range of principles and of ethical standards. How is a psychologist or counselor to choose from among them? Virtues have differed dramatically over the course of history and from culture to culture. Are there virtues that can be considered as common among humans, let alone psychologists? While there is room for discussion, Meara, Schmidt, and Day selected four virtues as possible common virtues, two of which have to do with how people conduct themselves and two of which pertain to how people interact with others.

The first self-pertaining virtue is *prudence*. Prudence is defined as the combination of abilities that allows one to make plans, to exercise good judgment, to work hard and with foresight, and to prioritize

---

## VIRTUE ETHICS

---

Ethics can be considered in a variety of ways: as a set of ethical codes, as a decision-making model, or as a set of principles. For example, other entries in this volume discuss ethics from all of these perspectives. There is typically a set of common principles that underlie these

long-term outcomes over short-term gains. For a counselor or psychologist to behave in an ethical manner, even within codes, standards, or principles, actually requires the virtue of prudence, because ethical dilemmas require prudence for their resolution.

The second virtue regarding the self is *integrity*. The value of integrity is contained in the ethical codes and standards of any profession, as the value means to perform actions for the right reasons and to avoid actions that are wrong or are performed for wrong reasons. People who have integrity make decisions over a period of time that reflect an integration of a coherent set of moral values and actions.

*Respect* is the third virtue and the first of two that focus on others. When a person respects another person, the first person gives the second person regard, attention, consideration, and worth. Respect denotes an appreciation for the intrinsic value of the other person regardless of his or her outward signs of value.

The last virtue is *benevolence*. Benevolence is defined as wanting to do good, to contribute to the well-being of persons and communities, to enhance the welfare of others, and to have social responsibility. Benevolence exists in most ethical codes and principles as well as decision-making models as a prime requirement. For a counselor or psychologist to be oriented toward the client requires benevolence.

Virtue ethics is a significant contribution to discussions on ethics, because it allows a consideration of the role of culture in defining ethical virtues, and it creates a climate in which the interaction of the individual within the community is considered in resolving ethical dilemmas.

## ABUSE

---

Abuse refers to physical, sexual, or emotional harm to a person perpetrated by a relative, caregiver, or spouse, or others in a social relationship with the abused person. Common forms of abuse include intimate partner abuse, partner or marital rape, and elder abuse. All of these forms of abuse are typically contained within the broad term *domestic violence*.

In many cases, survivors of sexual abuse, physical abuse, intimate partner violence (IPV), or elder abuse may be referred to counseling and therapy by law enforcement or other professionals, such as medical doctors and nurses, social workers, police officers, and the court. Counselors should be aware that a client may live in the same household with the abuser at the time of referral; therefore, the client may be afraid or ashamed to disclose the abuse because of economic dependency or fear of further physical or psychological harm from the abuser. It is important for therapists working with abused clients to first ensure their physical safety. It is critical to acknowledge that the cause of the abuse resides in the person who abuses rather than in the survivor. Therapists may effectively use techniques from many therapeutic orientations when working with abused clients, as long as they possess sufficient knowledge of the nature of the abuse, consequences of abuse, available services and resources for treatment, and legal issues.

### Intimate Partner Abuse

Intimate partner abuse is interpersonal violence that occurs between current and former marital partners,

cohabiting partners, separated marital partners, or same-sex partners. Several terms are used to describe violence or abuse between intimate partners. These include *marital abuse*, *spouse abuse*, and *domestic violence*. However, the terms *intimate partner abuse* and *intimate partner violence* are more commonly used today. Intimate partner violence occurs among heterosexual and same-sex partners as well as across different racial and ethnic groups. It is estimated that IPV occurs in 10% to 20% of intimate couples in the United States. Some research suggests that the prevalence rate may be higher among some marginalized groups, including couples that cohabit without marriage, rural populations, disabled individuals, and recent immigrants.

Violence against intimate partners includes physical violence, sexual violence, threats of violence, stalking, and psychological abuse. Each act can be placed on a continuum ranging from mild verbal abuse to severe physical violence and even partner homicide. Men and women are equally likely to be initiators of IPV; however, women are more often survivors of severe violence resulting in injury and death.

In addition to physical injury, negative consequences of IPV include psychological stress and financial costs in lost wages and medical fees for treatment. Survivors of IPV often experience strong psychological stress such as helplessness, fear, anger, and anxiety. Some survivors may develop nightmares, intrusive thoughts, intense anxiety, and fears associated with violence. These are common symptoms of posttraumatic stress disorder. Survivors of repeated violence may develop learned helplessness, a psychological condition in which survivors no longer attempt to escape from a painful situation because of previous failed

attempts. These strong emotional stressors may further impair survivors' cognitive and coping skills and even diminish survivors' abilities to leave abusers.

IPV increases the cost of mental and medical health care and shelter services. Violence occurring between intimate partners is the number one cause of injury for women in the United States. Those injured in severe physical or sexual violence often need immediate medical attention. Multiple medical care visits may occur as a result of each violent incidence. Furthermore, female survivors of intimate partner violence suffer more reproductive health problems, sexually transmitted diseases, and unwanted pregnancies than other females. For some survivors, psychological stress due to living in a violent home environment can develop into physical illnesses such as headaches and back pain. In addition to medical costs, intimate partner violence also increases the need for mental health services. Nearly one third of female intimate partner survivors report using mental health counseling, often with multiple visits. For physically injured survivors, violence may mean a loss of productivity from both paid work and household chores. In some cases, survivors may lose their employment or become homeless due to the victimization or attempts of escape from abusers. In fact, family violence is one of the major causes of female homelessness in the United States, and shelter services are required as a result.

### ***Explanations for Intimate Partner Violence***

Risk factors are factors that have been shown to increase the likelihood of involvement in IPV victimization or perpetration. A combination of individual, relational, cultural, and social factors contribute to the risk of involvement in IPV. Identifying risk factors can be useful in prevention and intervention. However, it is important to remember that risk factors are not causes of violence and they do not predict who will become involved in IPV.

IPV occurs in every racial and socioeconomic group, although it is more prevalent among families with low socioeconomic status. In addition, younger partners (age 16 to 24) appear to be the most violent. Exposure to parental violence and childhood abuse increases the likelihood of becoming a perpetrator and a survivor of intimate partner violence. Children who are exposed to parental violence may learn to use violent acts as a means of conflict resolution with intimate partners.

Drug and alcohol abuse are frequently associated with IPV. Men with alcohol problems are more likely to perpetrate intimate partner abuse than those who do not abuse alcohol or other substances. However, not all perpetrators have histories of alcohol or drug problems. Therefore, some research suggests that the relationship between alcohol consumption and partner abuse may be accounted for by antisocial personality traits rather than drinking behavior alone. In fact, a significant proportion of IPV perpetrators report more depression, lower self-esteem, and more aggression than do nonviolent intimate partners. Evidence indicates that violent intimate partners may be more likely than others to have personality disorders or attachment problems.

Cultural acceptance of violence has been associated with IPV, especially patriarchal attitudes that assume men's power over women and their right to control their female partners. Higher IPV rates occur among women who have little work experience and are dependent on their male partners for financial resources. However, the cultural value of patriarchy is not the sole cause of IPV.

### ***Reasons for Leaving or Remaining in an Abusive Relationship***

Even though "just leaving" seems a simple solution for terminating an abusive relationship, the decision survivors make to leave or remain in an abusive relationship is complex. Some internal barriers and external considerations may slow the process. In fact, it often takes several attempts before survivors permanently terminate their abusive relationships. Even though most women eventually terminate abusive relationships, research has found it is a difficult, stressful, and often dangerous process. In addition, counselors should not assume that leaving is the preferred intervention; for many survivors, this is not a desirable option, and their therapists should work from a harm reduction model.

Internal factors, such as low self-esteem and self-blame, denial of the abusive nature of the relationship, and emotional dependence may play a significant role in abused partners remaining in an abusive relationship. Many IPV survivors want to remain in the relationship, but have the battering stop. Research suggests that changes in beliefs regarding the likelihood of this wish are needed in order for IPV survivors to leave an abusive relationship. Survivors may experience events that act as a catalyst, leading them

to the realization that the relationship will not improve. Following this realization, survivors may give up the dream of an idealized committed relationship and search for ways to safely leave the abuser.

In many cases, violent relationships are maintained through power and control. The abused partner may depend on the abuser for basic economic needs. Some IPV survivors remain in the abusive relationship simply because they have nowhere to go. They may not have economic resources, social support, or shelter information. Furthermore, leaving an abusive partner can be a dangerous process. When survivors try to leave their violent partners, perpetrators frequently threaten to harm the survivor or survivor's children and family. Since laws often fail to protect survivors attempting to leave an abusive relationship, many survivors experience an increase in victimization when they attempt to leave. Therefore, it is important for counselors not to guarantee the safety of a client who is leaving a relationship; rather, they should assist in helping the client establish as many safeguards as possible during the transition.

Male IPV survivors may have additional barriers because traditional male gender roles emphasizing strength and independence may hinder them from reporting violent acts and seeking help. In addition, there are indeed fewer shelter resources and treatment groups available for male survivors of interpersonal violence. Similarly, sexual minorities may find a lack of services for treatment, given that many interventions and shelters were created from a male heterosexual perpetrator model.

### ***Counseling Concerns***

The primary counseling concern for survivors of IPV is their physical safety. Safety plans are strategies counselors can use to help survivors develop means of protecting themselves and their children during an abusive incident or when preparing to leave an abusive relationship.

A safety plan for survivors to use during an abusive incident includes staying out of rooms with no exit and staying away from rooms in which potential weapons may be accessible, such as the kitchen. Survivors can invent code words that alert friends, children, neighbors, or family to call the police. A safety plan for survivors preparing to leave an abusive relationship involves such strategies as the client's opening a checking account in her or his own name and involving

people or agencies that may be helpful. Survivors should prepare an extra set of keys and a bag packed with necessities, and should have important documents stored in an undisclosed location such as a friend's home. Because many IPV survivors have limited financial resources, it is important to help them achieve economic independence by means such as obtaining temporary welfare benefits and improving their job-finding skills. Shelter treatments provide survivors with a temporary separation from abusers and assist them in developing safe leaving plans. Survivors may receive help from domestic violence programs or shelter workers to obtain restraining orders or other legal procedures and counseling and educational services. It is important to help clients establish a record of physical abuse by their partners, such as filing restraining orders, phoning 911 when incidents occur, and keeping photographs and other evidence (e.g., threatening or controlling letters).

If the abuser has left the shared residence, safety plans include changing locks on doors and windows, changing telephone numbers, screening calls and blocking caller ID, obtaining an order of protection, and inserting a peephole in the door. In addition, it is important to make sure that schools and day care centers know who is allowed to pick up the children. In terms of safety on the job and in public, survivors should be advised to keep orders of protection with them at all times. They should call police immediately if the abuser violates the order of protection. It is desirable to change regular travel routes and try to get rides with different people. Clients should let supervisors, human resource personnel, and/or security guards know about the situation and how to respond should the abuser show up at the workplace.

IPV survivors may recover from victimization through empowerment. Some IPV survivors may not be able to distinguish the differences between normal and abusive relationships; they may perceive their abusive situations as normative. Counselors help survivors realize that they are not the cause of the violence or the ones responsible for stopping the abuse. It is also essential for counselors to help survivors identify their strengths and help them develop coping skills so that survivors become more assertive and make self-directed decisions. In addition to individual therapy, survivors can be empowered by learning and supporting one another in a group setting. Group members may gain the awareness that their situation is not unique and they are not alone; they may be

inspired by senior members who have made substantial progress; they may benefit by the chance to help and support other group members; and they may learn interpersonal and social skills during the course of therapy. Another important counseling concern is to help IPV survivors establish support systems. Social support networks are one of the most essential elements in helping survivors leave their abusive relationships. Survivors with diminished or nonexistent support networks are more likely to return to their abusers. Counseling should help survivors establish support systems from family members, friends, and religious groups.

Counselors need to possess knowledge about community resources, including social, psychological, healthcare, legal, and political services. The healthcare community should regularly screen clients for IPV. Once IPV survivors have been identified, they should be provided information and referred to appropriate agencies. If IPV survivors have drug or alcohol abuse problems, therapy addressing substance abuse should be considered. If survivors have prior victimizations, such as childhood sexual or physical abuse, therapists may help survivors process their early abuse experiences in relationship to their current abusive relationship.

Counselors need to possess additional knowledge when working with survivors with diverse backgrounds. For example, physically disabled survivors may need transportation assistance in order to access community services or go to court buildings. Lesbian IPV survivors may have limited support from family and peers who may not want to shed negative light on the lesbian community. Immigrant women may have difficulty understanding English and need interpreters.

### **Sexual Assault and Intimate Partner Rape**

Sexual assault is any type of sexual act that is not consensual. These acts can be physical, verbal, or psychological and include inappropriate touching, attempted rape, and rape (e.g., vaginal, anal, or oral penetration). Often, sexual assaults are perpetrated by someone the survivor knows, such as a spouse, family member, date, coworker, friend, or acquaintance. If sexual violence occurs between intimate partners, it is often referred to as a form of intimate partner violence. Individuals may be forced into unwanted sexual activities because of threats or intimidation from the perpetrator, or they may be under the influence of

drugs or alcohol and unable to give consent. Some individuals are unable to give consent because of age, physical disability, or mental illness. Although anyone can be a potential victim of sexual assault, females are the most common victims of sexual violence. Young women, women with physical and mental disabilities, and women living with limited economic resources are at higher risk.

Sexual assaults by intimate partners are often more violent, cause more injuries, and have a longer-lasting negative impact on survivors than sexual assaults by acquaintances. Aftermath effects may include emotional shock, panic, guilt, anger, denial, and/or feelings of powerlessness. Some survivors of sexual assault experience intense fear and nightmares associated with their victimization. Other short-term and long-term effects of sexual violence include gynecological problems, gastrointestinal disorders, substance abuse, somatic conditions, depression, eating disorders, high-risk behaviors, and suicidal thoughts and attempts.

### **Counseling Concerns**

Psychological first aid immediately after a sexual assault is essential to help survivors recover from the victimization. Counselors need to be sensitive and provide support to survivors. Survivors of sexual assault should be advised to receive medical attention and report the assault. Preventive treatment for sexually transmitted diseases and administration of emergency contraception may be considered. Hospital emergency rooms have standard procedures for assisting survivors of sexual assault, such as collecting medical evidence or DNA samples for criminal prosecution. Additional information about legal services should be offered.

Counselors should make clear to sexual assault survivors that they are not to blame for the incident, even if they were attacked by an acquaintance, date, friend, or spouse; had sexual relations with the person before; were under the influence of alcohol or drugs; or were wearing clothes that society may consider seductive. No matter what the previous situations or circumstances were, they were assaulted if they were unable to say “no” or to physically fight back.

Counseling can help survivors understand the course of recovery from sexual assault, help them process and express their feelings, and encourage them to seek support from friends and family who can validate their feelings and affirm their strengths. Survivors can benefit from techniques that help them

reduce anxiety, such as relaxation exercises, walking, yoga, music, reading, and hot baths. Journaling may also be a means for survivors to release feelings. Group therapy may provide an opportunity for survivors of sexual assault to normalize their feelings of guilt and shame and support one another.

Male survivors of sexual assault may experience additional emotional stress, as there are myths that only women are sexually assaulted, only gay men are assaulted, and men cannot be assaulted by women. These myths can further increase the emotional pain and shame that male sexual assault survivors may experience and increase their feelings of isolation. For these reasons, male survivors are less likely to seek help and report their crimes. Heterosexual, gay, and bisexual men are all potential victims of sexual assault. Being a victim is a difficult concept for most men to accept. Therefore, male survivors may define their assault as a loss of masculinity and blame themselves. In response to feelings of guilt, shame, and anger, some male survivors may engage in self-destructive behavior such as exhibiting more aggression, increasing drug and alcohol use, or withdrawing from social relationships. Some male survivors experience sexual difficulties after being assaulted, because negative feelings associated with sexual assault may be triggered by intimate sexual contact. They may have difficulty resuming sexual relationships or starting new ones after the assault.

For both heterosexual and gay men, sexual assault can lead to questions about their sexuality. Heterosexual men may feel confused about their sexual orientation after a male-perpetrated assault if they believe that only gay men will be sexually assaulted. Therefore, clients should be made aware that sexual orientation is unrelated to the experience of being sexually assaulted. For gay men, sexual assault may lead to feelings of self-blame attached to their sexuality. Some gay men with internalized homophobia may believe that somehow they deserved the assault. It is important to reassure survivors that sexual assault is an act of violence, power, and control and that no one engages in any behavior to provoke it. Gay men may also be less likely to report the assault due to fears of blame by police or medical personnel, resulting in insufficient treatment for the incident.

## Elder Abuse

Elder abuse refers to intentional or unintentional acts by caregivers or other persons that cause harm or a

serious risk of harm to a vulnerable adult. This abuse can happen to men and women, people of all ethnic backgrounds and social status, and gay, lesbian, bisexual, and transgender elders. The 1987 Amendments to the Older Americans Act was the first time the federal government defined elder abuse, neglect, and exploitation. These definitions, however, served only as guidelines for identifying elder abuse. Currently, elder abuse is defined by state laws, and these definitions vary by state in terms of what constitutes elder abuse. The broad definition of elder abuse includes physical abuse, emotional or psychological abuse, sexual abuse, financial or material exploitation, neglect, self-neglect, and abandonment.

*Physical abuse* consists of using enough force to cause unnecessary pain or injury to an elderly person. Physical abuse can range from slapping, shoving, and restraining to severe beatings. *Emotional* or *psychological abuse* occurs when a family member or a caregiver acts in a way that causes an elder person emotional distress or fear. The abuse can range from verbal assaults and threats of physical harm to isolating elders from other family members or regular social activities. *Material* or *financial exploitation* includes the misuse or exploitation of older adults' material or monetary assets. *Sexual abuse* consists of any sexual activity for which an elder does not consent or is incapable of giving consent. The sexual activity can range from exhibitionism to fondling to oral, anal, or vaginal intercourse. *Self-neglect* is when elder persons fail to meet their own physical, psychological, and social needs due to illness, dementia, substance abuse, depression, and/or poverty.

Elder abuse falls into three basic categories: domestic, institutional, and self-neglect or self-abuse. *Domestic abuse* constitutes maltreatment by caregivers in the elder's or caregiver's home. *Institutional abuse* occurs in elderly care facilities, such as nursing homes, group homes, and board and care facilities. Sometimes elders neglect their own care, which can lead to illness or injury. *Self-neglect* can include behaviors such as not eating or drinking, leading to dehydration; poor hygiene; and failure to take medications. For some elders, the problem is coupled with Alzheimer's disease or dementia, isolation, depression, and declining health. It is debated whether self-neglect is abuse, because the elder person chooses to neglect his or her own needs. Therefore, there is controversy over whether involuntary intervention should be implemented for elder people who engage in self-neglect.

Elder abuse is a complex issue. There is no single explanation for elder abuse, and many factors may contribute to its occurrence. The unique ways in which these factors interact with each other depends on the home environment of the perpetrator and victim of elder abuse. These factors may include family characteristics, caregiver issues, and the levels of dependency and impairment of the elderly people involved.

Elder abuse may be an extension of the family's violent interaction behavior. Intergenerational violence may perpetuate elder abuse. Family stress and caregiver stress are often associated with elder abuse. Caring for a mentally-impaired or physically-ailing older adult is highly stressful. Caregivers who do not have sufficient information, skills, or financial and psychological resources may find caring extremely challenging and stressful, which may lead to abusive acts.

Some caregivers who are at risk for abusing elders have their own psychological maladjustment or difficulties. Caring for an elderly person demands psychological and physical energy, and caregivers who have emotional or substance abuse problems may have limited ability to cope with stressful life situations. Caring for an elderly person may exacerbate their psychological vulnerability and lead to abuse. Caring for an elderly person also requires financial resources. When a family is financially struggling, the family may fail to provide adequate care for an elderly family member. For some families, financial exploitation may occur when the family is financially in need or economically dependent on the elderly person. Social isolation is another risk factor for elder abuse because without social support and outside help, the care of an elderly person can increase the stress level of caregivers. If abuse does occur, social isolation may prolong the occurrence of the abuse since no one outside the family is aware of the abuse.

Certain societal attitudes toward elders may hinder the prevention and termination of elder abuse. Some members of society may devalue or lack respect for elderly people. The problem of elder abuse is not widely publicized or understood. In addition, given the strong emphasis on personal and familial privacy, elder abuse is often hidden within the family. Furthermore, abused elders commonly feel too humiliated or fearful to talk about the abuse; this lessens the possibility of intervention to stop the abuse.

The most important step in elder abuse prevention is acknowledging human dignity, which exists

regardless of a person's age and level of physical and psychological functioning. The media should offer positive images of elder lives and increase public awareness of elder abuse. Social resources and support groups need to be available to elderly individuals and their family members. Counseling and treatment resources should be available for families caring for elderly people. Mental and medical healthcare workers play a vital role in assisting elder abuse survivors, and regular medical screening of possible elder abuse is vital for detecting potential abuse. If suspicion of abuse arises, a call to local or state agencies may help stop future abuse.

## ACADEMIC ACHIEVEMENT

---

An achievement test is any test designed to assess an individual's attainment of a specific knowledge or skill in a specified content area within which the individual has received some level of instruction or training. However, achievement tests are often confused with aptitude tests. Aptitude tests may not differ in form from achievement tests, but they typically differ in both use and interpretation. Aptitude tests are typically designed to estimate an individual's future

performance on a task and/or his or her aptitude to develop new skills or knowledge if provided instruction or training. Essentially, achievement tests assess current performance after specific training; aptitude tests assess the potential for future performance.

For more than 100 years, achievement and aptitude testing have steadily gained momentum and support from psychologists, educators, policymakers, and the general public. Recent laws at both federal and state levels clearly demonstrate the emerging importance of achievement and aptitude testing in a data-driven political system. However, regardless of such apparent support, considerable confusion remains about the nature, use, and appropriate interpretation of achievement tests.

### Aptitude Testing

Because achievement and aptitude tests are frequently used in combination with one another, a brief discussion of aptitude tests is warranted. The Sixteenth Mental Measurements Yearbook (MMY) groups aptitude and ability tests into a single classification (i.e., Intelligence and Scholastic Aptitude) that includes measures of general or specific knowledge and aptitudes or cognitive abilities. As mentioned, aptitude tests are essentially measurements of an individual's performance on a selected task or tasks, which are then used to predict that same individual's future performance. They can assist external parties in predicting performance in selection processes, and help individuals gain a better understanding of their abilities in making life decisions (e.g., career or educational choices). The MMY includes a plethora of assessments under this category, including those of verbal and nonverbal reasoning; critical, abstract, and creative thinking; cognitive and mental abilities (including traditional intelligence tests); memory aptitudes; and learning aptitude, potential, and efficiency.

The predictions made from aptitude test results are not always limited to tasks or situations that are similar to those initially measured. In fact, some aptitude tests focus on predicting seemingly unconnected tasks and skills, while others are used to predict future performance in entirely different situations. For instance, high school students interested in particular careers might be given aptitude tests to measure their aptitudes for those careers. The students' test results can then be used to help advise them about available academic or training programs beyond high school

(rather than simply whether they should actually pursue the specified careers).

Aptitude tests can also vary in the number of aptitudes measured by a single instrument. *Multiaptitude batteries* are aptitude tests that measure a broad array of ability areas (e.g., verbal reasoning, numerical reasoning, and mechanical reasoning) during a single administration. These batteries are used primarily for intellectual, educational, and vocational assessment, and they are well suited to show individuals' relative strengths and weaknesses. For that reason, multiaptitude batteries are generally more useful in career and academic counseling than are single-aptitude assessments.

One of the more common multiaptitude batteries is the Armed Services Vocational Aptitude Battery (ASVAB), which was first developed in 1966 and is now on forms 23 and 24. Most, if not all, new recruits to the U.S. Armed Forces take the ASVAB. It measures aptitudes for general academic areas and career areas that are involved in most civilian and military careers. Scores from the eight subtests can be used to locate possible career options in OCCU-FIND—a manual listing more than 400 occupations, including about 150 military careers.

Although multiaptitude batteries are more useful than single-aptitude tests in certain circumstances, there are also instances in which more specialized aptitude tests are preferable. For instance, broad-based multiaptitude tests such as the Wechsler Adult Intelligence Scale (WAIS) can predict a variety of cognitive and mental aptitudes. However, they do not measure all possible cognitive abilities, and they do not necessarily provide the most accurate predictions of future performance in specialized tasks, such as mechanics, art, and music. In fact, the MMY provides a classification of specialized assessment instruments (e.g., fine arts, mathematics, reading, science, and social studies) and lists both aptitude and ability tests within each group. The following examples provide some indication of the broad array of specialized aptitude tests available to psychologists:

- The Mechanical Aptitude Test is a 45-minute test that measures high school students' and adults' mechanical abilities, such as comprehension of mechanical tasks, use of tools and materials, and matching tools with operations.
- The O'Connor Finger Dexterity Test assesses psychomotor aptitudes (i.e., ability to perform bodily

movements), and it is used to predict how well a person would be able to perform certain motor tasks in various situations (e.g., working on a rapid assembly, performing watch repair).

- The Meier Art Tests are examples of specialized assessments for artistic aptitude. Among these tests is one for Aesthetic Perception. This test presents an examinee with four versions of the same artistic work that differ along an important aesthetic dimension (e.g., proportion or form). The individual ranks the works in order of merit, and the results can be used to predict the individual's future success in tasks involving these aesthetic concepts.
- The Seashore Measures of Musical Talents is a 60-minute assessment of musical aptitude. The assessment battery includes a listening test with six subtests measuring dimensions of auditory discrimination (e.g., pitch, loudness, rhythm, and tonal memory).

### Hybrid Testing

Admissions tests are some of the most commonly used assessments within the realm of aptitude and achievement tests, yet they are also the most difficult to define according to traditional definitions. Confusion can arise when applying the standard definition of either achievement or aptitude tests to scholastic assessments, because scholastic ability/aptitude tests combine the predictive goals of aptitude tests with the performance assessment goals of achievement tests. As such, it is not uncommon for classification systems to place admissions tests into a hybrid category.

The SAT is one of the three most common admissions tests, and a prime example of such confusion about whether admission tests are achievement or aptitude tests. Originally introduced in 1901, the SAT is now taken by over 2 million students annually and is accepted by nearly every American college and university as the entrance examination component of the admissions process. The debate about the purpose and usefulness of the SAT led to several changes in its name throughout the 20th century. The SAT was first introduced as the "Scholastic Achievement Test," renamed the "Scholastic Aptitude Test" in 1941, and became the "Scholastic Assessment Test" in 1990. Following the 1994 revision, and continuing with the most recent 2005 revision, "SAT" is no longer an acronym. The test is presently known as the "SAT Reasoning Test."

The other widely used hybrid tests are the ACT and Graduate Records Examination (GRE). Similar to the SAT, the "American College Test" was renamed "ACT" in 1996. Most American colleges and universities use the ACT and GRE, respectively, to make decisions about the admission of applicants to undergraduate and graduate programs of study.

### Achievement Testing

Although hybrid tests incorporate elements of achievement tests, more traditionally defined achievements tests are clearly differentiated from aptitude and ability tests. The focus of achievement tests on measuring acquired knowledge makes them the primary type of instrument used in educational programs at all levels. Although this essential element is consistent across achievement tests, these tests can be further categorized using several nonexclusive characteristics.

#### ***Standardized Versus Nonstandardized Achievement Tests***

One characteristic that can be used to distinguish among achievement tests is whether the test has been standardized. *Standardized achievement tests* are those that have been administered, revised, and tested to establish an average level of performance. Standardization allows an individual's test results to be compared to those of other test takers. Because the individual's achievement is compared to that of a reference group, scores on standardized achievements tests are generally indicated by a percentile rank. Scores may also be indicated using grade-level equivalency (e.g., an eighth-grade student scores a 10 on a standardized achievement test, indicating that she scored as well as the average tenth-grade student).

Although standardized tests are generally considered more robust and valid measures of achievement, the majority of achievement tests used in educational settings are nonstandardized. Such *nonstandardized tests* include exams, tests, and other instances where the intent is to simply indicate how much an individual learned, without referencing a specific performance standard established by a reference group. Toward this end, nonstandardized tests essentially assess individual achievement as a proportion of the maximum potential level of achievement, as defined by the trainer, educator, or external test developer. Nonstandardized tests can be scored more subjectively (e.g., essay tests and

short answer tests) or more objectively (e.g., multiple choice and matching tests), but the ultimate score will always be a proportion of the total potential achievement. Typically, scores are reported as pass or fail, a percentage of the total possible score (e.g., 93% out of possible 100%), a letter grade (e.g., A, A-, B), or a number grade (e.g., 17 out of 32).

### ***Norm-Referenced Versus Criterion-Referenced Achievement Tests***

As mentioned above, standardized achievement tests require referencing an individual's performance to an established standard level of performance. There are two methods for establishing these standardized performance levels: norm referencing (also known as *nomathetic* and *standards* referencing) and criterion referencing (also known as *idiographic* and *domain* referencing). *Norm-referenced* achievement tests compare each individual's achievement to the achievement of others taking the same measure. As such, achievement level is based on the average performance of the norm group, rather than on the actual percentage of correct answers. In order to enhance such comparison of individual scores to the norm group, norm-referenced tests are typically created to mimic the normal curve. Individuals are then provided a scaled score or percentile rank according to the normal curve. Some of the most common norm-referenced tests are the California Achievement Test (CAT), Comprehensive Test of Basic Skills (CTBS), and Tests of Academic Proficiency (TAP).

There are several criticisms of norm-referenced achievement tests. For instance, because norm-referenced achievement tests are designed for national or international use, there is a possibility that the content being tested is not covered by the education or training actually provided to the individual. When this difficulty becomes salient, instructors sometimes change the material they teach, which leads to the criticism that some instructors are "teaching to the test." In addition to content, critics note that the norms of many achievement tests are too old to measure achievement according to current standards and/or teaching methods. Furthermore, the norms may be too limited to provide meaningful normative comparisons for all demographic groups, specifically those of culture or ethnicity. There are also arguments that such assessments may sacrifice accuracy or breadth in order to ensure that examinees' scores conform to a

normal distribution. In addition, a mathematical property of the normal curve is that changes in the number of correct answers do not lead to the same change in the percentile rank for all individuals. These arguments have led major test makers to address criticisms through redesign and/or renorming of their achievement tests, and to emphasize that norm-referenced achievement tests should not be the sole basis for making critical decisions about students' retention or graduation.

Although most achievement tests are norm referenced, their limitations have led to the continued use of criterion-referenced tests in certain situations. *Criterion-referenced* tests compare each individual's performance to a predetermined standard or criterion level, rather than a norm group. They focus on mastery of a given objective or skill, and typically include many items measuring a single objective. Because criterion-referenced tests are scored against an absolute standard, usually the percentage of correct answers, criterion-referenced tests are more common in the daily assessment of individuals in educational settings. Unlike norm-referenced achievement tests that force individuals into a normal curve, criterion-referenced tests do not limit the number of examinees that can demonstrate outstanding performance and mastery.

In an effort to draw upon the strengths of both norm-referenced and criterion-referenced tests, some achievement tests incorporate both standardization procedures. Scores on such tests are reported in terms of both how the examinees compare to others and how well they mastered the assessed content. For instance, the TerraNova (also known as the California Achievement Test, Sixth Edition or CAT/6) indicates both a student's grade equivalency and that student's level of mastery.

### ***Individually Versus Group-Administered Tests***

The majority of achievement tests can be administered to a group of individuals. This is particularly useful in educational settings where thousands of students might take the same instrument within a similar time frame. However, information such as behavioral observations can be obtained only during an individual test administration. Individualized achievement assessment is particularly useful for assessing the vocational rehabilitation of adults and learning disabilities of children and adolescents. There are

several individually-administered achievement tests, as well as many that can be administered either to individuals or to groups.

### ***Survey Achievement Batteries***

Achievement tests also vary in terms of the number of achievement domains being assessed. Survey achievement batteries, which assess a broad array of areas, are the most widely used format. The survey achievement battery typically has a number of subject-based subtests. They are most commonly used to assess achievement in the areas emphasized in K–12 education, thereby providing educators with information about student achievement across the educational curriculum with a single administration. One of the most popular of the survey achievement batteries is the Iowa Test of Basic Skills, designed for students in kindergarten through Grade 8. This battery assesses achievement in areas such as vocabulary, reading comprehension, language, mathematics, spelling, science, maps and diagrams, and reference materials.

### ***Examples of Achievement Tests***

While there are hundreds of achievement tests, the following provide examples of the more frequently administered instruments:

- The Woodcock-Johnson® III (WJ III) is a widely used comprehensive system (i.e., hybrid battery) for measuring general intellectual ability (or *g*), specific cognitive abilities, scholastic aptitude, oral language, and academic achievement. These variables are measured through two distinct batteries: The WJ III Tests of Cognitive Abilities and the WJ III Tests of Achievement. The WJ III can be administered to any individual over the age of 2. Because of its breadth and its assessment of achievement, the WJ III is often used to diagnose learning disabilities, guide educational programs, assess growth, and identify discrepancies between an individual's levels of aptitude and achievement.

- The Wechsler Individual Achievement Test—Second Edition (WIAT–II), is a test of reading and mathematics achievement that is suitable for individuals age 4 and older. The WIAT–II evaluates both the correctness of the response and the process by which the examinee arrived at the response, thus allowing for a more accurate assessment of problem-solving skills than other achievement measures. The WIAT–II

is also conformed with the Wechsler Intelligence Scale for Children—Fourth Edition (WISC–IV), which is the most commonly used test of intellectual and cognitive functioning for children.

- The Wide Range Achievement Test 4 (WRAT4) is designed to assess individuals between the ages of 5 and 75. The WRAT4 assesses the achievement of reading, spelling, and arithmetic skills.

- The Kaufman Test of Educational Achievement, Second Edition (K-TEA II) provides a broad assessment of academic achievement. It can be administered in a longer (five-subtest) comprehensive form or a brief (three-subtest) screening form to students in first through twelfth grade. Both the comprehensive and brief versions provide an assessment of key academic skills in reading, mathematics, written language, and oral language.

### ***Federally Mandated Statewide Achievement Tests***

On January 8, 2002, the No Child Left Behind Act of 2001 (NCLB) was enacted, which emphasized standards and accountability with educational systems. The NCLB was intended to hold states, school districts, and schools accountable for the adequate education of American youth. Specific initiatives within NCLB were designed to assess and reduce the achievement gaps that existed between ethnic/racial minority students and majority group students, and among students from differing socioeconomic statuses. The NCLB act created the necessity for an ongoing assessment of achievement on a national scale.

Since 1969, the National Assessment of Educational Progress (NAEP) has provided the only national assessment of students' achievement in major academic areas. However, the NAEP originally assessed only a national sample of fourth-grade students every 2 to 4 years. Currently, under the NCLB, the NAEP assesses a national sample of fourth- and eighth-grade students every 2 years. However, there are clear limitations of such a national norm-based test. In particular, it is impossible for a single measure to accurately test all individual academic standards as defined by each state's education department. As such, the NCLB requires all states and territories receiving federal funding to develop and implement a procedure to independently obtain achievement data on all public school students.

The purpose of the state assessment requirement is to provide an independent, objective measure of the educational progress of each student, school, school district, and state/territory. These assessments are expected to measure how well each student achieves the individual state's academic standards in reading, mathematics, and science. Academic standards have been developed by every state to indicate what students at particular grade levels should learn in specific subject areas. The underlying assumption is that students will perform well on the state achievement tests if teachers are competent and cover the material required by the standards. Hence, education departments argue that there should be no need to "teach to the test" and/or engage in specific test preparation or coaching.

The NCLB mandates that the state assessment procedure must include at least one criterion-referenced or norm-referenced assessment, may include multiple assessments, must address the depth and breadth of the state academic standards, and must be reliable and valid. Because all students are expected to achieve the same high levels of learning, the NCLB requires states to hold all public elementary and secondary school students to the same academic content and achievement standards. Thus, the same rigorous test must be used throughout the entire state. Beginning with the 2007–2008 academic year, all states must administer annual achievement tests for reading/language arts and mathematics in each of Grades 3 through 8, and at least once in Grades 10 through 12. In addition, annual achievement tests for science must be given at least once in each of the following: Grades 3 through 5, Grades 6 through 9, and Grades 10 through 12.

As with other high-stakes tests, data obtained from state achievement tests can have a significant effect on the future of the test takers. Aggregated results can have subsequent effects on schools, school districts, and even states. The most basic use of statewide achievement tests is to provide teachers and administrators with information about individuals, and tailor services to address a student's demonstrated difficulties. The "high stakes" designation of such achievement tests comes from the fact that many states use a student's performance to determine whether students have gained enough knowledge to progress to the next grade level. Although the *Standards for Educational and Psychological Testing* stress the importance of taking into consideration several points of data when making such decisions, many states consider achievement test results to overrule all other measures.

Statewide achievement data can also provide information on the curriculum being used and the quality of instruction being provided. In this way, the statewide assessment also becomes "high stakes" for teachers and their curriculum. Poor results could indicate a need to revise the curriculum to better achieve the desired academic standards, or a need to provide the teacher with additional training to improve the quality of instruction. In some states, teachers who have a large percentage of low-achieving students may be removed from their positions, as may principals and superintendents. Conversely, teachers who have a large percentage of high-achieving students sometimes receive additional monetary compensation as a reward for their success.

Statewide assessments also become "high stakes" for the schools and school districts themselves, as the NCLB requires that the scores of all eligible students be aggregated to determine whether the school or school district made "adequate yearly progress" during the course of a specified period of time, generally 2 years. In so doing, the state specifies a minimum level of improvement in student performance that schools must achieve. This minimum is based on the performance of the lowest-achieving demographic group or lowest-achieving schools in the state. The state then sets a threshold for adequate progress, and this threshold is raised at least once every 3 years. The goal is that, at the end of 12 years, all students in every state will demonstrate adequate levels of achievement on the respective state assessments. Schools that do not make adequate yearly progress can be required to develop a corrective action plan or to fund options for students to attend another school or to receive additional tutoring. In addition, the school district could initiate a restructuring that results in the replacement of all or most of the staff, or in the assumption of school operations by the state or a private company.

### ***Pitfalls in Statewide Achievement Testing***

Although achievement tests have demonstrated usefulness in a variety of situations, controversy and criticisms still exist about how these tests are developed, standardized, and utilized. One such criticism is that improvements in the reliability, accuracy, and validity of many achievement tests have narrowed their range of application. For instance, some test developers have improved norm referencing by standardizing their tests on multiple norm groups based on

age, ethnicity/race, and seasonal norms. As a consequence, each form of the test is applicable to a more narrowly defined group. Therefore, it is important to select achievement tests that reliably and validly measure the intended subject and that yield results that are generalizable to the population being tested.

Although achievement tests are useful tools to help guide decisions, one of the strongest criticisms of achievement testing surfaces when educational decisions are made solely upon the basis of achievement test results. Such criticism becomes particularly salient when critics focus upon differential treatment of cultural groups (e.g., ethnicity, income level, special needs). For instance, the American Civil Liberties Unions (ACLU) has expressed concern about the federal requirement that the same test be given to those with special needs and/or limited English proficiency. Other critics argue that achievement tests do not uniformly indicate achievement across other cultural groups, such as ethnicity and gender. Although well intended, such criticisms are generally antiquated, as development or revisions of the most widely used achievement tests have addressed many previous criticisms about the differential applicability to various populations. Indeed, meta-analyses on hundreds of thousands of examinees indicate that the most widely used achievement tests do not differ in their predictive accuracy as a function of ethnicity or gender.

More specific to statewide achievement testing, critics have argued that such assessments evaluate the curriculum and instructional method used by teachers, rather than students' abilities to learn the information provided. Such critics argue that negative consequences of achievement test results (e.g., holding a student back a grade) could punish the student for the failure of the school or teacher. Critics further argue that this becomes particularly problematic in the nation's poorest schools, where the quality of education is substantially lower than in more affluent schools. Although there is little research to refute the claim that curricula and teacher quality are positively correlated to student achievement, counterarguments to such criticism often reference research studies and meta-analyses that reveal a plethora of other variables affecting student achievement. Such variables include per-pupil expenditures, larger class sizes, parent involvement, student motivation, school attendance rate, and student satisfaction with school. Furthermore, it is important to note that the intent of statewide achievement testing is not to make educational

decisions for individual students, but to identify schools and school districts that require additional assistance and/or resources to ensure students make gains in academic achievement.

Because achievement tests can only measure a limited amount of information, they are unable to assess the full range of information learned by the student or the ability of the student to apply information they have learned in real-world situations. Related to this, critics argue that achievement tests lead teachers to overemphasize memorization and de-emphasize thinking and the application of knowledge. Because of the limited nature of achievement tests, "teaching to the test" can be effective in increasing achievement scores, but it also narrows and weakens academic curricula. Critics argue that this can lead schools to remove courses that do not clearly promote the rote memorization necessary to score high on achievement tests (e.g., physical education, art, and music). Indeed, as the federal government has defined "improvement" in terms of achievement test results and has tied funding to this definition, critics argue that schools are shifting from education to test coaching. That being said, proponents of statewide achievement testing note a distinct difference between "teaching *to* the test" and "teaching *the* test," the former being when teachers align their curriculum to proven indicators of student success and the latter being when teachers provide only the exact information on the test. Indeed, proponents argue that teaching knowledge and skills based on a standard curriculum with specific indicators, which are then assessed by the achievement test, is considered "curriculum alignment" and is believed to lead to higher quality schools and curriculum.

## Conclusion

For more than 10 decades, achievement and aptitude tests have gained popularity and drawn considerable attention from psychologists, researchers, educators, and the general public. Although initially achievement tests were heavily criticized and limited in their applicability, the past four decades have seen dramatic improvements in their quality, reliability, validity, and generalizability. Such improvements have been further enhanced and expedited by state and federal funding in the wake of federal law requiring the statewide achievement testing of all public school children. Psychologists and educators can now choose from hundreds of research-based achievement tests with

demonstrated reliability and validity. It is not surprising that the growing popularity and the high-stakes nature of achievement testing in many settings (e.g., educational, forensic, diagnostic) has led to new criticisms and a rehashing of older criticisms. However, nearly every criticism of achievement testing has been largely refuted by psychological and educational research. Ultimately, when selected, applied, and interpreted appropriately and professionally, achievement tests provide the best means for the assessment of acquired knowledge and skills of all individuals in a wide variety of settings.

## ADAPTIVE BEHAVIOR TESTING

---

Adaptive behavior is the extent to which an individual demonstrates the culturally established standards for effective personal independence and social responsibility needed for daily living. This includes how well an individual manages the demands of day-to-day functioning (e.g., hygiene, domestic chores), motor functioning (e.g., ambulation), and communication (e.g., receptive and expressive language). It also includes cognition (e.g., problem solving, managing finances) and social functioning (e.g., use of leisure time, maintaining friendships). The American Association on Mental Retardation explains that adaptive behavior involves three broad areas: Conceptual (e.g., language and academic skills); Social (e.g., interpersonal skills, obeying laws); and Practical (e.g., self-help skills and occupational skills). Adaptive behavior can be contrasted with intellectual functioning, which involves problem solving, reasoning, conceptual thinking, and learning efficiency. Although they represent different constructs, intelligence and adaptive functioning are moderately correlated (around .3 to .4), and the correlation between these constructs increases with the severity of intellectual and adaptive impairment. This suggests that intelligence and adaptive functioning are not totally independent constructs.

### Assessment

Formal adaptive behavior assessment typically involves using a norm-referenced instrument to obtain information about how well the individual functions independently at home, school, and in the community. Typically this information is obtained from an informant (e.g., parent, teacher, or guardian) using an interview format. The instrument is normally administered, scored, and interpreted by a school psychologist, school counselor, or special education teacher if the individual is in school or by a clinical psychologist or social worker if the individual is out of school or is an

adult. In all cases the examiner must have specialized training to interpret the data.

There are six or eight adaptive behavior scales, and most take approximately 1 hour to administer and score. Unfortunately, different adaptive tests and different informants can yield different scores. Therefore, the first goal of any examiner is to select a psychometrically sound instrument and interview an informant who is very familiar with the individual being evaluated. Regional differences regarding which adaptive scale to use are common and are often due to personal preferences, the influence of training programs, and access to updated norms (i.e., revised editions). Frequently used adaptive scales include the Scales of Independent Behavior-Revised (SIB-R), the Vineland Adaptive Behavior Scales, Second Edition (Vineland-II), and the Adaptive Behavior Assessment System-Second Edition (ABAS-2). Most adaptive behavior instruments have a number of subscales or subtests that measure four to six broad areas of independence. For example, the SIB-R has four factors (Motor Skills, Social Interaction and Communication Skills, Personal Living Skills, and Community Living Skills) that are combined to yield a Broad Independence score. The Vineland-II has four adaptive scales (Communication Skills, Daily Living Skills, Social Skills, and Motor Skills) that are combined to produce an overall Adaptive Behavior Composite. Several of the instruments have maladaptive scales to allow the clinician to better understand the individual's disruptive, uncooperative, or inappropriate behaviors needing targeted intervention. Results from the adaptive behavior instruments are reported in the form of standard scores that have a mean of 100 and a standard deviation of 15. Typically, scores in the range of 85 to 115 are considered age appropriate or "average."

## Applications

Adaptive behavior assessment has been used in conjunction with intellectual assessment in the diagnosis of mental retardation for decades. The American Association on Mental Deficiency (now the American Association on Mental Retardation) included deficits in adaptive functioning in its first definition of mental retardation in 1959. Similarly, in public schools, according to the Individuals with Disabilities Education Act (IDEA), children are diagnosed with mental retardation and provided specialized programming when both their intellectual functioning and their

adaptive behavior functioning fall at least two standard deviation units below the mean. For most IQ and adaptive behavior tests, this involves standard scores 70 and below. In nonschool settings, such as mental health, Mental Retardation/Developmental Disabilities (MRDD) facilities, and community living settings, the clinicians are obligated to use the *Diagnostic and Statistical Manual, Fourth Edition, Text Revision (DSM-IV-TR)* criteria for mental retardation before assigning the diagnosis. This definition requires both intellectual and adaptive behavior functioning two standard deviations below the mean. In both settings, the adaptive behavior test results are used diagnostically (i.e., to determine whether there is a diagnosis of mental retardation), descriptively (i.e., to determine the person's strengths and limitations), and prescriptively (i.e., to determine the appropriate goals for intervention programming).

While adaptive behavior assessment historically has been employed with persons suspected of having mental retardation, it is used to obtain valuable information for many students and adults referred for cognitive, academic, and/or behavioral assessment. For example, adaptive behavior testing provides valuable insight into the manifestations of developmental delay, pervasive developmental disorders, autism, and various behavior disorders. The results can be helpful in establishing intervention goals and in guiding treatment efforts. Ultimately, adaptive behavior testing is useful in helping a wide range of individuals achieve more satisfying, productive, and independent lives.

## ADLERIAN THERAPY

---

Adlerian therapy refers to counseling and psychotherapeutic interventions that are associated with the individual psychology of Alfred Adler (1870–1937), a Viennese psychologist and contemporary of Sigmund Freud. *Individual psychology* emphasizes an examination of the individual's social and cultural embeddedness, a holistic view of personality, taking personal responsibility, striving to achieve life goals, growth towards a sense of completion and belonging, and a practical approach to meeting life's challenges. Because these values are so universally shared, a wide variety of mental health professionals use classical and contemporary expressions of Adlerian therapy in their work.

### Theoretical Basis of Adlerian Therapy

Adler believed that people's pursuit of their overarching life goals pulled them from positions of inferiority, inactivity, and inertness to positions of mastery and completion. Many factors affect the nature of people's life goals and the manner in which they pursue them, including heredity, pre- and perinatal influences, socioeconomic and cultural contexts, health, the family emotional environment, and school experiences. In the process of negotiating these goals, Adler contended, all people must address three tasks: how to find a productive work role in life, how to establish

and maintain an emotionally close relationship with a life partner and family members, and how to contribute meaningfully to the community of humankind.

Adlerian therapists believe that *social interest* leads to and is a marker of psychological health. The essence of social interest involves striving to achieve one's life goals while meeting life's tasks in a socially responsible and supportive manner. Some individuals, however, strive so single-mindedly after particular goals, which offer only a fleeting sense of efficacy or esteem, that life tasks go unmet and other people are viewed as obstacles that must be manipulated, mastered, or vanquished. This approach is the antithesis of healthy mental functioning.

Adler believed that the roots of unhealthy goal striving developed during childhood from a confluence of variables such as dysfunctional family environments that were discouraging and disempowering, undiagnosed or untreated psychological or medical conditions, and lack of encouragement. Such conditions overwhelm the child's ability to develop a healthy lifestyle and a sense of belonging. Rudolf Dreikurs, an Adlerian scholar, observed that under these circumstances children may act out or misbehave as a means of seeking attention, becoming more powerful, exacting revenge, or withdrawing from a task or interaction. Adults also may develop self-defeating life goals that give rise to physical or psychological symptoms and to interpersonal difficulties. Adlerian therapy seeks to determine the early-in-life causes of unhealthy, self-defeating life goals, and to reorient the individual toward a healthy style of life.

### Processes of Adlerian Therapy

Dreikurs identified four phases that characterize Adlerian therapy. The initial phase involves establishing the therapeutic relationship. This is done by enlisting the client's cooperation, addressing and resolving immediate crises, understanding the presenting problem, and identifying possible goals for the therapy.

The second phase of therapy involves the use of semistructured interview and standardized measures to assess the client's lifestyle (i.e., personality). The lifestyle assessment process provides the clinician with essential information and creates an experience of self-discovery for the client. A successful lifestyle assessment will reveal the client's *private logic* (i.e., the reasons underlying the client's thoughts, emotions, and behaviors). Adlerian therapists sometimes

use genograms to explore the structure and emotional atmosphere of the client's family of origin and to understand the client's early goals and sense of belonging. The client's perceived position in his or her family may provide an indication of how he or she relates to others. Early recollections of childhood events and the analysis of dreams can reveal the client's implicit life goals. Knowledge of the client's goal striving provides an overarching framework for understanding the finer details of the client's life.

The insight phase of Adlerian therapy involves helping clients build a deeper, intuitively-based awareness of their private logic so that behavior change can be implemented. Adlerian therapists use a variety of techniques at this stage of therapy, including challenge, confrontation, prescribing the use or display of a client's symptom, and "spitting in the soup" (i.e., making a preferred but dysfunctional goal or behavior less palatable to the client and thus making it less salient for dealing with life challenges). This phase culminates with the client's understanding how his or her life goals and subsidiary behaviors lead to problems and dysfunctional relationships.

The objective of the final phase of Adlerian therapy is to help clients reorient themselves from dysfunctional positions in life to individually healthy and meaningful life goals that embody social interest. A variety of techniques are used to help clients achieve this objective. For instance, Harold Mosak's pushbutton technique helps clients see that they have a choice about the particular thoughts they entertain, along with the ensuing emotions and behaviors that stem from them. Clients also can be taught to "catch oneself" and to change course when they realize they are pursuing a goal or enacting a behavior that has been identified as dysfunctional. Clients can experiment with new modes of being and new life roles by "living as-if" in progressively wider settings outside of therapy. Adlerian therapy concludes when presenting problems have been resolved and the client is able to derive the positive psychological benefits of pursuing healthy and meaningful life goals.

### Forms of Adlerian Therapy

Adlerian therapy is widely used in the treatment of adults, children, couples, families, and groups. Although many variations of Adlerian therapy exist, they differ primarily with respect to the duration of therapy, the focus and scope of treatment goals, and

the strategies and techniques that are afforded by the therapeutic modality. Adlerian therapy has traditionally been long term and comprehensive in focus, but clinicians have successfully adapted the approach for short-term and brief therapy.

Adlerian therapy with couples emphasizes how *complementarity* (i.e., compatibility) in the life goals and lifestyle of the partners can perpetuate relational discord. Therapy with couples is aimed at increasing the partners' awareness of the way in which their choices lead to disagreements and unhappiness instead of goal alignment, mutual support, and encouragement.

Adlerian therapy with families emphasizes the importance of a democratic and supportive family atmosphere, the role of the parents as leaders and caregivers, the individual responsibility of each family member, and the necessity for each person to contribute meaningfully within the family system. Adlerian therapists often include the Systematic Training for Effective Parenting (STEP) model that was created by Don Dinkmeyer, Sr., Gary McKay, and Don Dinkmeyer, Jr. as an important component in primary and secondary prevention efforts with families.

Adlerian therapy with children uses a variety of play and other nonverbal techniques to examine the sources of a child's symptoms and goals. In addition to resolving symptoms (e. g., school refusal or aggressiveness), Adlerian therapy emphasizes the importance of orienting children toward cooperation (versus competition), and of encouraging them to become socially interested (versus self-interested). Adlerian interventions with children frequently involve parents and family members.

Adlerian group therapy, with suitably-screened clients, provides an active therapeutic forum in which the social manifestations of client's problems (e.g., goals for dominating others, hesitating lifestyle tendencies) can be explored and changed. Adlerian groups accentuate the client's social embeddedness, the interpersonal nature of problems, and ways in which social interest can be cultivated.

### Current Status and Future Trends

The breadth of Adlerian therapy makes it conceptually and clinically resonant with classic therapeutic approaches (e.g., those of Karen Horney, George Kelly, Abraham Maslow), with modern cognitive-behavioral approaches (e.g., those of Albert Ellis,

Aaron Beck) and with the newer postmodern and constructivist perspectives on therapy (e.g., that of Robert Neimeyer). The latter group has found Adlerian therapy of particular interest because of a shared epistemological heritage in the work of Hans Vaihinger's *Philosophy of the As-If*.

Mental health professionals continue to find Adlerian therapy and individual psychology highly useful to their work. The *Journal of Individual Psychology* is the primary forum for disseminating the conceptual and clinical scholarship of the field. Books summarizing the Adlerian literature or focusing upon specific topics continue to appear regularly. For example, Henry Stein and his associates have undertaken a comprehensive project to translate Adler's papers on theory and practice from their original German into English. The North American Society for Adlerian Psychology organizes an annual international convention dedicated to the advancement of Adlerian theory and therapy. The International Committee for Adlerian Summer Schools and Institutes (ICASSI, [www.icassi.net](http://www.icassi.net)) provides training in Adlerian methods and offers a framework for advocating positive social change in accordance with the work of Adler and Dreikurs. A number of local Adlerian societies and training institutes exist throughout the world.

## AFFECT (MOOD STATES), ASSESSMENT OF

In psychology, the term *mood* refers to a person's emotional state. Mood is central to psychological health, and disturbances in mood are related to subsequent psychological maladjustment. Moods such as elation, joyfulness, and excitement, when experienced within normal ranges, enhance a person's life and are associated with well-being. Moods such as anger, hostility, depression, and mania are negative emotions. When these moods are experienced outside of the normal range or when a person no longer has control over these moods, psychological disturbances appear in behavior. While it is normal for persons to experience anger, irritation, or sadness based on external events, these emotions can become extreme, leading to the need for psychological intervention.

A client's mood permeates almost any aspect of psychological intervention, and hence a reliable assessment of mood is part of the psychologist's armamentarium. The most common methods of assessing mood are the clinical interview and the use of a self-report inventory, but some psychologists use projective tests to assess mood. Although there are psychologists who tend to rely on their own clinical judgments and avoid more formal assessments, a

formal and organized assessment typically provides more accurate information than interviewing a patient in an unstructured manner. A systematic assessment evaluates all aspects of mood, whereas an unstructured assessment guided by clinical judgment can become sidetracked on a particular line of inquiry and fail to assess all aspects of the problem.

This entry reviews the instruments and scales most commonly used by psychologists to assess disturbances in mood. Some of these use a true/false format, others have a checklist format, and still others have a multiple-choice format, but the format is less important than the range of content included in the instrument. Some of these instruments are referred to as *broad-band* instruments because they assess a variety of emotions. Others are referred to as *narrow-band* tests, signifying that they assess only a single specific mood.

When assessing moods, psychologists consider whether the respondent is reporting honestly or is faking a response (i.e., exaggerating or underreporting his or her problems and emotional state). Inaccurate or “faked” responses are more likely when an evaluation is conducted to decide about employment, child custody, or prison release, or to obviate or attenuate a court verdict.

Some tests and scales include items that are both obvious and subtle to control for faking. An obvious item is one where the content of the item is logically related to the mood being assessed. For example, “I feel blue most of the time” is an obvious item when assessing depression. A respondent motivated to fake a response could do so easily on such an item. However, if research has found that depressed respondents often answer, “False” to the item “I like to eat candy,” the item is not obviously related to depression (i.e., provides a subtle assessment of depression). In general, tests and scales that have ways to detect tendencies toward inaccurate or inconsistent responding are more valid than those without such means.

Finally, psychologists evaluate the psychometric properties of tests and scales prior to using an instrument. *Psychometric properties* refer to the reliability, validity, internal structure, and correlations with external behavior of scores on the scale. All of the measures reviewed in this entry have acceptable reliability and validity.

The temporal reliability of an instrument is particularly important when assessing mood, because the respondent’s score at different times is often important. If the construct is a trait, temporal stability is

expected. If the construct is a mood, the pattern of change provides information about the improvement or lack of change in the emotional state.

## Methods of Assessing Mood

The most common way to assess mood is the clinical or assessment interview. Mood is an element in the overall assessment process in almost every published recommendation on interviewing and is a routine part of both a psychiatric and a mental status examination. These can be structured clinical interviews or “naturalistic” interviews. The latter are more commonly referred to as *unstructured interviews*, in which the psychologist talks with the client about a variety of topics and in so doing ascertains the level of mood (also referred to as *affect*).

Two types of structured interviews have been published. In a *structured clinical interview*, such as the Structured Clinical Interview for DSM–IV, the psychologist asks a predetermined set of questions. No additional questions are permitted. The client’s responses are scored according to diagnostic criteria. In a *semi-structured clinical interview*, such as the Structured Interview for DSM–IV Personality, the psychologist asks a set of predetermined questions, but supplements them with unscripted follow-up questions—referred to as *probes*—to gain a more complete understanding of the client’s response. In conducting an unstructured or semistructured interview, psychologists also take into account the client’s body language.

A clinical interview may appear to be unstructured because the psychologist does not appear to ask a set of predetermined questions. Nevertheless, the skilled interviewer will make sure to ask questions about each of the areas regarded as relevant to the question, problem, or disorder at hand.

There are many published self-report inventories that assess mood. Following is an overview of some of the more popular broad-band and narrow-band instruments that assess moods that have particular relevance to client functioning and behavior (i.e., anxiety, depression, mania, and hostility).

## Broad-Band Mood Survey

The Guilford Zimmerman Temperament Survey (GZTS) is a 300-item self-report survey designed for use with individuals 16 years of age and older who have at least an eighth-grade education. It takes from

30 to 60 minutes to complete and can be scored via local software, mail-in scoring, or optical scan scoring. It provides scores on 10 aspects of personality and temperament (e.g., energy versus inactivity, impulsivity versus restraint, friendliness versus hostility, and stability versus irritability). A computer-derived interpretive report is available from the publisher. The GZTS was designed for use in counseling, career planning, personnel selection, and placement with nonclinical populations.

### **Broad-Band Measures of Anxiety**

The scales discussed below are embedded in larger instruments. They are rarely extracted from the parent instrument for administration independent of the larger test.

#### ***Anxiety-Related Scales From the Minnesota Multiphasic Personality Inventory-2 (MMPI-2)***

Four scales of the MMPI-2 assess the respondent's anxiety level—one clinical scale (Psychasthenia, or Pt), two content scales (Anxiety and Fears), and one supplemental scale (Welsh's Factor A).

*Psychasthenia* is an older term that means neurotic anxiety, as opposed to realistic anxiety. It has been removed from psychiatric nomenclature, but the scale remains on the MMPI-2 as scale Pt. It is a 48-item scale that assesses trait anxiety, self-dissatisfaction, and psychic distress. The scale provides a reliable measure of both state anxiety (i.e., temporary anxiety due to some external circumstance) and trait anxiety (i.e., a lasting personality characteristic).

The Anxiety content scale consists of 23 items that assess physiological symptoms of anxiety (e.g., shortness of breath, sleep disturbances, and heart palpitations) and cognitive signs of anxiety (e.g., edginess, tension, and a fear that you are losing your mind). Persons who obtain a high score on this scale are described as ruminative, intellectualizing, and engaging in ritualistic behaviors. They often report problems with concentration, worry needlessly, and are troubled by disturbing thoughts. Scores on this scale are quite consistent when the test is administered more than once within a short period of time, such as a week.

The 23-item Fears content scale assesses apprehension about a particular object or circumstance and a fear of harm or injury. It has two components. The

Generalized Fears component measures respondents' feelings of persistent danger, and the potential harmfulness of objects or environmental circumstances. The Multiple Fears component assesses more specific fears such as fears of common objects or circumstances.

Welsh's Factor A scale represents one of the primary components underlying responses to the MMPI-2. It assesses situational stress rather than generalized trait anxiety measured by the Pt scale, and is commonly interpreted as a measure of generalized anxiety. The scale is sometimes described as measuring lack of ego resiliency or general maladjustment.

#### ***Anxiety Clinical Scale From the Millon Clinical Multiaxial Inventory***

The Anxiety Clinical Scale from the Millon Clinical Multiaxial Inventory (MCMI-III) contains a 14-item scale that correlates positively with items dealing with general distress and is useful in diagnosing patients with an anxiety disorder. Item content deals with nervous tension, intrusive thoughts (particularly over upsetting or traumatic events), sweating, compulsive behaviors, excessive worry, and fears of being alone. Persons scoring high on this scale have symptoms associated with physiological overarousal. They are described as anxious, apprehensive, restless, unable to relax, edgy, jittery, and indecisive. They often report symptoms that include insomnia, muscular tightness, headaches, nausea, cold sweats, undue perspiration, clammy hands, and palpitations. Phobias may or may not be present.

#### ***Anxiety Scale From the Personality Assessment Inventory***

The Anxiety Scale from the Personality Assessment Inventory (PAI) scale measures the cognitive, affective, and physiological aspects of anxiety. PAI items deal with subjective feelings of apprehension, ruminative worries, and physical signs of tension and stress.

#### ***Anxiety-Related Scales From the Sixteen Personality Factors Questionnaire***

The 5th revision of Raymond Cattell's Sixteen Personality Factors (16 PF) contains two factor scales, Apprehension—(Factor O) and Tension—(Factor Q4), that measure anxiety and a secondary factor referred

to as Anxiety. Elevations on the Apprehension scale describe a person who complains about excessive worries, apprehension, guilt, and insecurities. Elevations on the Tension scale describe someone who is tense, driven, and frustrated and feels overwrought. The Anxiety secondary factor includes items that assess emotional stability and vigilance.

### **Anxiety Scales From the Symptom Check-List-90 Revised**

The Symptom Check-List-90 R (SCL-90-R) consists of a list of items that describe mood states (e.g., nervous, apprehensive). Respondents are instructed to check all of the items that describe them. The test is designed for use with adult patients and nonpatients and takes about 12 to 15 minutes to complete. The items are written at the sixth-grade reading level, and those on the anxiety scale assesses typical symptoms of anxiety, such as feelings of dread and terror, apprehension, tension, trembling, and general nervousness and panic. The Phobic Anxiety scale of the SCL-90-R measures persistent fears—of persons, places, objects, or situations—that are deemed irrational and that lead to avoidance or escape behaviors.

## **Narrow-Band Measures of Anxiety**

### **Beck Anxiety Scale**

The Beck Anxiety scale has 21 obvious items that are rated by the respondent on a 4-point scale. For example, the scale asks such questions as whether the respondent feels like a failure, cries a lot, or feels like killing him- or herself. Consequently, the scale is more susceptible to faking than are the scales mentioned above. Administration time is approximately 5 to 10 minutes.

## **Broad-Band Measures of Depression**

### **The Depressive Adjective Check List**

Adjective checklist methodology directs respondents to endorse an adjective if it describes them and to leave the item blank if it does not. Among the more popular instruments of this kind is the Depression Adjective Check List (DACL). The DACL was developed to measure transient moods, feelings, and emotions related to depression. It requires an eighth-grade reading level and has been translated into many foreign languages. There are several available lists to

choose from with each list taking from 2 to 3 minutes to complete. Thus an assessment can be performed quickly and with minimal client resistance. Norms have been published for both depressed patients and normal individuals reporting no symptoms requiring attention. Items pertain to positive (e.g., happy) and negative (e.g., hostile) moods.

The Multiple Affect Adjective Check List-Revised (MACL-R) consists of 132 adjectives that ask respondents about their present state (i.e., “How do you feel today?”) and their more enduring trait (i.e., “How do you generally feel?”). It requires a sixth-grade reading level and measures both positive affect (e.g., friendliness, affectionate, and loving) and negative affect (e.g., anxiety, depression and hostility). It comes in two alternate forms.

These adjective checklists have the advantage of brevity and rapid administration. They consist of non-intrusive items that use words that are familiar to clients and a nonthreatening test format. They possess high face validity (i.e., they look like they are measuring what they claim to measure), and thus they stimulate little client test-taking resistance.

### **The Depression-Related Scales of the MMPI-2**

Two scales of the MMPI-2 provide measures of depression. The Depression (D) clinical scale is a 57-item scale that contains items dealing with subjective depression, psychomotor retardation, physical malfunctioning, mental dullness, and brooding. The major theme in this scale is psychic distress. This scale is sensitive to mood changes—a feature that makes it useful for detecting actual variations in mood.

The Depression (DEP) content scale consists of 33 obvious items that deal with distressed mood. The scale items assess lack of drive, self-depreciation, exaggerated feelings of discontent, and suicidal ideation.

The D and DEP scales differ in the emphasis they give to different symptoms of depression. The items on D refer predominantly to vegetative symptoms (e.g., problems with lack of energy, sleep, and poor appetite). Items that ask about cognitive symptoms of depression (e.g., feeling like a failure, feeling useless, and feeling lonely) have a secondary role. Scale DEP does not contain any items dealing with vegetative symptoms. All of the items assess cognitive symptoms of depression such as feelings of worthlessness, inadequacy, and inferiority.

### ***The Depression-Related Scales From the MCMI-III***

The MCMI-III contains three scales that assess for problematic mood. The 14-item Dysthymia scale asks about the absence of pleasure, loss of energy, guilt feelings, sadness, changeable moods, and general disparagement. The 17-item Major Depression scale assesses loss of energy and appetite, problems sleeping, general fatigue, absence of pleasure, feelings of emptiness, intrusive memories, suicidal thoughts, admission of past suicide attempt(s), and reports of repression. Finally, the Bipolar: Manic scale contains 13 items dealing with overactivity, elation and inflatedness, flight of ideas, variable moods, overtalkativeness, and impulsivity. The Depressive Personality Disorder scale assesses a clinical personality pattern rather than mood, but there is much redundancy between the personality disorder and mood scales.

### ***The Depression Scale of the PAI***

The PAI Depression scale (24 items) is designed to measure clinical depression. Item content pertains to both cognitive symptoms (e.g., unhappiness, pessimism, apathy, and negativism) and physical symptoms (e.g., problems with sleep, appetite, and energy). There are three subscales dealing with cognitive, psychological, and affective aspects of depression.

### ***The Depression Index From the SCL-90-R***

The Depression scale from the SCL-90-R measures common symptoms of depression, such as lack of interest, lack of motivation (apathy), suicidal ideation, withdrawal, extreme discontent and negative affect, and various bodily symptoms of depression.

### ***The Depression Index From the Rorschach Inkblot Test and Other Measures of Affect***

The Rorschach inkblot test can be scored to yield scores that pertain to the affect of depression and one major index that assesses depression.

One ratio is the relationship of form-color responses to color-form and pure color responses. A form-color response is one that describes an object that has a distinct shape and which also uses color to describe the percept. An example would be “a yellow banana.” This measures controlled emotions. A color-form response is one where the object seen is dominated primarily by its

color rather than by its form. An example would be “looks like a blue sky.” When the respondent refers only to the colors of the inkblot in forming the response, then a pure color response is scored. The last two types of responses measures impulsivity. The Affective ratio is the number of responses to the last three Rorschach cards compared to the number of response to the first seven cards. This measures the degree to which the client tends to become impulsive and drawn into emotional situations. Pure color is scored when the respondent only uses color to form the percept and indicates a failure to modulate an experienced emotion. Because many of the inkblots are black appearing on a white background, sometimes the respondent uses the white space rather than the black inkblot to form a response. This is called a space response. Space responses are scored when the test taker only uses this white space in the card to form the response. Depending on the frequency of occurrence, they can mean pessimism and negativism. The Depression Index (DEPI) clusters these and other scores into an overall index of depression. Since extensive training is required to reliably score and interpret the Rorschach, most psychologists use quicker and more objective means to assess mood.

## **Narrow-Band Measures of Depression**

### ***The Beck and Hamilton Depression Index***

The Beck Depression Inventory is a 21-item scale designed to assess clinical depression. Respondents rate each item using a 4-point scale. Since all of the items are obvious, the scale is prone to a faked-bad response set. That means that it is easy for respondents to fake responses to appear depressed when, in fact, they are not depressed, and vice versa. The Hamilton Depression Scale contains primarily items dealing with more vegetative symptoms of depression (i.e., sleep, appetite, and energy). The instrument can be used to screen for the more severe forms of depression.

### ***Measures of Mania***

Mania refers to an abnormally elevated mood that is often accompanied by both excessive cheerfulness and irritability. During a manic episode there is a decreased need for sleep, increased energy, rapid thought processes, excessive grandiosity, and distractibility. Depending on the severity of the condition, delusional

thinking may also be present. Mania differs from impulsivity in that there is a loss of self-control and a disturbance in emotions. Usually a period of deep depression follows the manic episode. This condition was known as manic depression but is now known as bipolar disorder.

### **Scale Ma From the MMPI-2**

The Hypomania clinical scale contains 46 items with four major content areas: amorality, psychomotor acceleration, imperturbability, and ego inflation. The major theme underlying these items is impulsivity.

### **Scale N From the MCMI-III**

The MCMI-III contains a 13-item Bipolar: Mania scale. Item content pertains to overactivity, elation and inflatedness, flight of ideas, variable moods, overtalkativeness, and impulsivity. Clinically elevated scores suggest a patient with labile emotions and frequent mood swings. During the manic phase, symptoms can include flight of ideas, pressured speech, overactivity, unrealistic and overexpansive goals, impulsive behavior, and a demanding quality in their interpersonal relationships.

### **The PAI Mania Scale**

The PAI Mania scale (24 items) assesses both mania and hypomania (i.e., an abnormality of mood resembling mania but of lesser intensity). Content addresses elevated mood, irritability, impatience, expansiveness, grandiosity, and exaggerated activity. The scale has three subscales addressing Activity Level, Grandiosity, and Irritability.

## **Measures of Hostility**

### **The Hostility Scale From the SCL-90-R**

The SCL-90-R Hostility scale addresses such things as anger, aggression, rage, and resentment, and more attenuated feelings such as thoughts of anger.

### **Cook-Medley Hostility Scale From the MMPI-2**

A hostility scale (Ho) based on the original item pool of the MMPI has been extensively researched as

a predictor of health outcomes and the physiological mechanisms underlying the association between hostility and health. These emotions play a role in coronary artery disease and the Type A personality style.

### **Megargee's Overcontrolled Hostility Scale**

This scale, developed from the MMPI item pool, was designed to differentiate between two types of violent criminal. Undercontrolled offenders are the type of aggressive, angry, physically violent individuals most readily recognized as dangerous by individuals and society in general. In contrast, overcontrolled offenders are seen as passive. They inhibit their aggressive impulses and generally are highly constrained until they engage in a violent physical assault. Those who knew these individuals viewed them as nice, polite members of society and are often stunned when learning of their violent behavior. The MMPI items that differentiated the undercontrolled individual reveal a passive and nonaggressive personality. Hence, the scale is labeled "overcontrolled hostility." The validity of this scale has been limited to an offender population.

## **Evaluation of Scales**

All of the scales discussed in this entry are psychometrically sound. They have acceptable internal consistency and test-retest reliabilities across a 1-week interval. Most of these scales are susceptible to faking because they contain obvious items dealing with the circumscribed mood. Some are embedded as scales in a large omnibus inventory. The effects of extracting these scales from their omnibus inventory and administering them separately are not yet well understood.

Some of these scales have a general mood scale that contains the major content components or dimensions of the mood, while others have subscales that assess specific components scale of these construct. The latter type of scale allows psychologists to check for differential endorsement of specific symptoms within a domain (e.g., endorsing cognitive but not physiological item). However, such differential endorsement is usually atypical.

These scales generally are quite adequate in doing what they are designed to do. There are very little differences between them that would warrant choosing one over the other. The choice of the scale depends on the needs of the psychologist, time considerations, the

setting and context in which the assessment occurs, and the motivation of the client.

## **BANDURA, ALBERT (1925– )**

---

Albert Bandura was born in 1925 in a small town in northern Alberta, Canada. He was the youngest of six children and the only son. The local schools he attended were very short of teachers, so the young students had to be self-directed in their learning. This may have been where the young Bandura began to learn what would become a central theme in his later research on human development and functioning, that of *self-directedness*, or *agency*. Bandura earned his B.A. in psychology at the University of British Columbia and his M.A. and Ph.D. at the University of Iowa. After receiving his doctoral degree in 1952, under the direction of Arthur Benton, he joined the faculty of the Department of Psychology at Stanford University where he has spent his entire professional career.

### **Early Social Learning Theory: The Importance of Observational Learning**

Albert Bandura is one of the founders of behaviorally-oriented approaches to behavior change, including behaviorally-oriented psychotherapy. The psychodynamic drive model dominated the field of psychotherapy when he began his academic career, so his early work was met with skepticism and resistance from the established psychotherapy community. Beginning with his landmark 1963 book *Social Learning and Personality Development*, coauthored with R. Walters, he proposed a learning model based on the important role of observational learning and the consequences of behavior. He then began a major program of research

focusing in particular on the role of *observational learning* (also known as *imitation* or *modeling*) on the behavior of children.

Bandura soon applied his work to the treatment of adults with phobias, first snake phobia and later the broader family of agoraphobias. The treatment that evolved was based on the idea of *guided mastery* and designed to decrease fears by gradually increasing the client's sense of confidence or mastery in the behavioral domain in question. This guided mastery involved successful exposures to the feared stimuli through modeling, for example, of the therapist successfully engaging in the feared behavior, along with exposure to a graded series of "approach" tasks.

### **The Emergence of Self-Efficacy**

While evaluating these guided mastery treatments, Bandura found that they often generalized to other domains of behavior. For example, clients successfully treated for an animal phobia often showed gains in social confidence and public speaking confidence. Bandura concluded that the success of the treatment was actually the result of increased *self-efficacy expectations* (i.e., an increased sense of confidence in one's own behavioral competencies) with respect to the target behavior (and often other domains of behavior). In the 1970s he proposed a theory of behavior change with self-efficacy as the underlying causal mechanism. He theorized that psychological treatments worked because and to the extent that they were successful in increasing clients' perceptions of self-efficacy with respect to target behaviors. Based on the assumption of self-efficacy as the underlying mechanism of change,

the counselor could design interventions designed to increase self-efficacy expectations.

Bandura noted in his 1977 book, *Social Learning Theory*, that *perceived self-efficacy* refers to “beliefs in one’s capabilities to organize and execute the courses of action required to produce given attainments” (p. 3). Higher levels of self-efficacy are postulated to lead to “approach” rather than “avoidance” behavior, to better performance of enacted behaviors, and to persistence in the face of obstacles and disconfirming experiences. Bandura’s theory identifies four sources of efficacy information that both lead to the initial development of efficacy expectations and can be used to increase them: *performance accomplishments*, *vicarious learning* (modeling), *emotional arousal* (anxiety), and *social persuasion and encouragement*.

The concept of self-efficacy expectations is now widely used to develop counseling interventions to help with a variety of types of problems, including low social confidence, difficulties in educational and career decision making, development and maintenance of healthy behaviors, and avoidance of risky behaviors such as drug and alcohol abuse and unsafe sexual behaviors. In adolescents, perceived self-efficacy for affect regulation has been found to be related to higher self-efficacy in managing academic development and resisting pressure to engage in anti-social behaviors. Perceived coping self-efficacy also has been found to be related to recovery from traumatic experiences such as natural disasters, terrorist attacks, and sexual and criminal assaults. Self-efficacy concepts have been used to facilitate exercise programs in the elderly, and to assist people with disabilities, female offenders, and battered women. Such interventions require, in essence, that the counselor design a program including elements of the four sources of efficacy information—new performance accomplishments (successes), modeling of new behaviors, anxiety management, and verbal persuasion, encouragement, and social support.

### **Social Cognitive Theory: An Agentic Perspective**

As his work evolved, Bandura expanded his focus to what he called *social cognitive theory*. This represents Bandura’s attempt to understand the core element of what it means to be human, which for Bandura is the quality of *human agency* (i.e., the capacity to exercise control over the quality and directions of one’s life).

There are four features of agency—intentionality, forethought, self-reactiveness, and self-reflectiveness.

*Intentionality* is the formulation of plans for future action. Intentions are action plans directed toward some future desired goals. In some situations, intentions must involve a collective or community if collective agency is to be served. *Forethought* is the anticipation of future events—projected goals toward which individuals guide their behavior and the anticipated outcomes of their behavior. These can also be called *outcome expectations* or *incentives*.

*Self-reactiveness* is individuals’ capacity to monitor and modify their behavior to serve goals and desired outcomes. *Self-reflectiveness* involves self-observation and self-examination, but those alone are insufficient. Plans require action in order to be realized. Self-reflectiveness also requires changes in behavior based on the self-observations. The individual’s self-efficacy beliefs are the most important basis for determining whether the individual will engage in the effective self-regulation of behavior.

Bandura and others are now applying social cognitive theory, including these four central elements, to a wide range of individual and societal issues that require agentic responses for adaptive functioning and adjustment. In addition, Bandura has written that the concept of agency can be applied beyond personal agency to agency by proxy and collective agency. *Agency by proxy* occurs when we rely on others to act in agentic ways to help us meet our goals. *Collective agency* occurs when we rely on socially coordinated and interdependent actions. Central to collective agency is *collective efficacy*, essentially the shared belief that a group can work together to achieve its goals. Bandura has discussed the usefulness of collective efficacy in understanding the effective functioning of the family unit, educational systems, business organizations, athletic teams, the military, and political systems.

### **Awards and Honors**

It is difficult to overestimate the impact of Albert Bandura’s work on the field of psychology in general and counseling in particular. His work on collective efficacy is now influencing fields such as political science, economics, and business. Not surprisingly, Bandura has received much recognition and many honors in his career. He has been elected president of the American Psychological Association and Western Psychological Association, and honorary president of the Canadian Psychological Association. He has been

awarded the Distinguished Scientific Contributions Award of the American Psychological Association, the William James Award of the American Psychological Society, the James McKeen Cattell Award for Distinguished Achievement in Psychological Science from the American Psychological Society, election to the American Academy of Arts and Sciences, and, most recently, the Gold Medal Award for Lifetime Achievement in the Science of Psychology from the American Psychological Foundation. He is the author of nine books and hundreds of journal articles and has served on the editorial boards of more than 30 journals. He continues to publish actively.

## BECK, AARON T. (1921– )

---

Aaron Temkin Beck is an American psychiatrist and the father of *cognitive therapy*—the most empirically supported form of psychotherapy to date. Beck was

born on July 21, 1921, in Providence, Rhode Island. He attended Brown University, majoring in English and political science. Beck graduated magna cum laude in 1942. He attended Yale Medical School and attained his M.D. in 1946. In 1954, Beck joined the Department of Psychiatry at the University of Pennsylvania. He is currently a Professor Emeritus at the University of Pennsylvania. He also serves as director of the Center for the Treatment and Prevention of Suicide, President of the Beck Institute for Cognitive Therapy and Research, and Honorary President of the Academy of Cognitive Therapy. Beck has published over 450 research articles and more than 17 books. He is listed among the 10 individuals who shaped American psychiatry and is considered one of the five most influential psychotherapists of all time.

In the 1960s, Beck was interested in validating various psychoanalytic concepts to make them more accessible to the scientific community. He made depression the focus of his research. Rather than finding evidence supportive of the psychoanalytic formulation that depression was a result of anger turned inward, Beck instead documented themes of rejection, defeat, deprivation, and sensitivity to failure in the thoughts and dreams of depressed individuals. Beck also noticed that depressed mood was typically preceded by very rapid negative thoughts and that by helping people to become aware of these thoughts, test their validity, and modify unhelpful cognitions, their depression would improve. This research spawned the beginning developments of cognitive therapy.

Cognitive therapy was originally developed for the treatment of depression but has now been applied successfully to a number of psychiatric conditions, including anxiety disorders, eating disorders, schizophrenia, personality disorders, substance abuse and dependence, bipolar disorder, couples therapy, and crisis management. The main assumptions underlying cognitive therapy are that cognition affects behavior, cognition may be monitored and altered, and helping individuals to alter the way that they interpret information can effect long-term change on their emotional and behavioral functioning and prevent the recurrence of psychopathology.

In addition to his contributions to the development and validation of cognitive theory and therapy, Beck has also firmly established himself in the area of test construction. Along with his colleagues, Beck has developed some of the most well-known and frequently utilized self-report instruments available for

research and practice. The most popular of these measures is the Beck Depression Inventory-II, which assesses the severity of depressive symptoms.

Beck's theory, research, and practice have garnered tremendous support in both the scholarly and therapeutic communities. Although they originated in attempts to understand psychopathology and personality problems, Beck's theory and therapeutic approach also have important implications for understanding everyday normative psychological functioning and for counseling psychology.

## BEHAVIOR THERAPY

---

Behavior therapy does not assume that, at their core, humans are inherently positive or negative. Behavior therapy assumes that, within biological constraints, humans are complex learners. Sometimes rich repertoires of positive behaviors are learned. Sometimes excesses (e.g., high anxiety or anger) or dysfunctional behaviors (e.g., substance use, aggressiveness, or inappropriate avoidance) are learned. Sometimes people have not learned needed behavior (e.g., job

interviewing or assertion skills). Human functioning is heavily influenced by past learning and the requirements of current environments. The nature of the fit of the person and situation is critical. People who have the requisite cognitive, emotional, and behavioral skills needed in the current environment are likely to function well, but problems occur when the fit of the person to the environment is poor. If learning is the primary source of difficulty, then new learning can be the solution. Therefore, the goal of behavior therapy is to help the client learn to stop behaving in a certain manner and start behaving in a more effective way.

Behavior therapy is rooted in models of learning. The client's current concerns are concretely assessed and learning-based interventions are designed for effective cognitive, emotional, and behavioral functioning. Behavior therapy is action oriented and most appropriate for clients with behaviors that need to be changed, rather than those seeking self-exploration or help with decision making. Behavior therapy can be integrated with other approaches (e.g., cognitive or family therapy). An extensive body of research evidence documents the status of behavior therapy as an empirically supported intervention. This entry describes three types of learning—classical conditioning, instrumental conditioning, and vicarious learning—and explains how these types of learning are applied in behavior therapy.

## Types of Learning

### *Classical Conditioning*

In classical conditioning, new situation-response associations are developed through temporal pairing of new situations with events that currently elicit a response. With repetition, people come to react with the old response in the new situation. Many counseling-relevant examples of classical conditioning involve emotional conditioning. For example, initially a person might find that public speaking arouses only mild anxiety. Then, while making a presentation, this person makes mistakes that lead to great fear and embarrassment. Oral presentations become paired with strong negative emotional reactions such that now the person is strongly fearful when preparing or giving a speech. Classically-conditioned fear has strong motivational properties, causing escape, avoidance, and other dysfunctional behavior.

## Operant Conditioning

In operant conditioning, behavior is learned and maintained by the consequences that follow the behavior. Some consequences are external (e.g., praise from another), whereas others are internal (e.g., anxious feelings). Consequences also differ in a temporal dimension; some occur immediately, while others are delayed. Sometimes a conflict between the immediate and delayed contingences is part of the problem (e.g., avoiding a test brings a student immediate anxiety reduction but later academic difficulties). Behavior that leads to positive events (positive reinforcement) or a reduction of aversive events (negative reinforcement) will be maintained or increased. Behavior that consistently fails to lead to reinforcement (extinction) will decrease. Behavior that inconsistently or intermittently leads to reinforcement will be highly resistant to extinction and likely to persist. Behavior leading to negative, unpleasant outcomes (punishment) tends to decrease. Punishing consequences can involve the presentation of something aversive (e.g., being yelled at) or the loss of something positive or pleasant (e.g., loss of privileges).

Events co-occurring with or preceding consequences (antecedents) trigger and guide behavior because they signal likely consequences. In summary, in operant conditioning, antecedent events (internal and external) activate a person's learned behavior. The positive, negative, or neutral consequences that follow the behavior strongly influence the person to continue or change the behavior.

## Modeling or Observational Learning

In modeling, information about behaviors and their consequences is learned vicariously through observations of the situations, behaviors, and consequences experienced by others. Modeling can lead to the acquisition of new behavior (response acquisition), an increase of available behavior presently not performed (response facilitation), or a decrease in behavior (response inhibition) due to the adverse consequences to the model.

These learning processes often operate interdependently. For example, a fear might be developed through classical conditioning or modeling. Defensive, avoidant, and other dysfunctional behavior may be strengthened due to powerful negative reinforcement effects of the fear reduction produced by these behaviors.

## Characteristics of Behavior Therapy

Behavior therapists attempt to understand behavior within these learning models and employ learning-based strategies to bring about positive change. This learning-based understanding of human behavior leads to some broad characteristics of behavior therapy.

### Behavioral Specificity

Learning can be very situation specific. A person may respond effectively in one situation and poorly in another. For example, clients may not be "unassertive." They may respond respectfully and appropriately with coworkers, anxiously and acquiescently with supervisors, and aggressively with intimate partners. A corollary is that behavior therapists do not conceptualize client concerns in terms of broad intrapersonal characteristics (e.g., low self-esteem or chronic anxiety). Instead, they see problems as happening in specific contexts. Sometimes, the range of contexts is quite broad, but behavior therapists try to understand client concerns in terms of specific contexts, forms of responding, and outcomes or consequences.

Because learning histories are so varied, behavior therapists do not assume that the same stated client concern results from similar factors in different clients. For example, three clients might present with social anxiety. One may have conditioned strong emotional/physiological arousal that interferes with functioning and leads to avoidance. Another may never have developed needed social skills and consequently suffers interpersonal rejection. A third may have adequate skills but excessively high performance expectations and be highly demanding and self-critical, thereby being overly vigilant and anxious. Similar problems may be due to very different factors and require quite different interventions.

### Behavioral Assessment†

Behavior therapists approach client concerns with a careful assessment of *antecedent-response-consequence cycles* to understand the meaning of the client's stated concerns. Behavioral assessment often involves detailed interviewing and exploration of specific examples. Since not all issues can be understood by talking about them, assessment often involves observation during *naturalistic conditions* (e.g., marital discussion), *simulations* (e.g., role-play of giving negative feedback), or *imagery review* (e.g., visualization of a recent social

encounter). With client permission, information may be obtained from others (e.g., parents, employers, teachers, or intimate partners). *Archival information* (e.g., nursing notes, school records) also may be sought. *Issue-specific questionnaires* (e.g., a speech anxiety or assertiveness questionnaire) may be administered. The results of these are not used normatively, but as samples of the person's report about responses in the situation.

Information from these various sources is integrated, and clients and therapists develop a detailed, shared behavioral understanding of the antecedent-behavior-consequence sequence that forms the client's concerns. This understanding also leads to ways of monitoring key elements (e.g., frequency of behavior, anxiety intensity ratings on 0–10 scale, daily completion of the Beck Depression Inventory), which furthers ongoing understanding and assists in evaluating therapy effectiveness.

### **Behavioral Interventions**

If behavior is primarily learned responding, then learning-based interventions that alter one or more element of the antecedent-behavior-consequence sequence should increase desired outcomes. Since internal responding (i.e., feelings, imagery, self-talk) follows the same learning processes, learning-based interventions also can be brought to bear on internal responses.

*Modifying Antecedents.* Problematic behavior often exists in complex chains of behavior, so altering antecedents can change behavior in a number of ways. One strategy is for the person to avoid cues for problem behavior (e.g., someone with a drinking problem not socializing with an alcohol-abusing friend, couples not discussing problems when they are tired or consuming alcohol). Another strategy is building in a pause or a time-out, thereby interrupting the chain of events leading to problem behavior. When clients are about to engage in the problem behavior (e.g., yelling at their children), they remove themselves from the environment so that they interrupt their automatic, overlearned behavior and it does not continue. The clients may rehearse effective behavior (e.g., calmly making a request of their children) during this pause as well.

A variant is for the client to record undesired behavior before engaging in it. The act of recording breaks up the chain of antecedents and provides greater control over the behavior. Some environments

trigger multiple, conflicting behaviors. For example, an insomniac may read, ruminate, worry, do work, watch television, and eat in bed, making falling asleep difficult. Such insomnia may respond to stimulus narrowing in which all behaviors, other than sleep and sexual activity, take place in other environments. Other problem behaviors that occur in many environments (e.g., overeating, sulking, worrying) respond to stimulus narrowing (e.g., engaging in them only at a specific place and time).

Another way of modifying antecedents is to explain to clients how to systematically present cues for the desired behavior. For example, depressed clients might place a colored dot on their watch and rehearse realistic, positive self-appraisals whenever they look at the watch. The social environment may be reprogrammed so that friends and family prompt desired behavior. Clients can also preprogram the environment to reduce problem-eliciting antecedents (e.g., removing alcohol or high calorie foods). The person's internal environment may be altered so that negative self-talk or feelings such as anxiety do not trigger problem behavior. Developing specific self-instructions for initiating desired behavior also can be effective. In summary, undesired behaviors can be decreased and desired behaviors increased by clients' systematically changing the antecedent events that prompt them.

*Modifying Behavior.* Sometimes the goal is developing new, effective behaviors (e.g., job seeking or parenting skills). Behavior therapists focus on identifying needed skill components and providing experiences in which those skills are rehearsed until clients can use them naturally. Two examples, relaxation coping and assertiveness skills training, are described below.

Highly anxious, stressed, or angry clients may not know how to calm themselves and use skills they have to cope with the situation. Relaxation coping skills programs address these deficits.

First, clients are taught to recognize the internal and external cues for problem emotions so they know when to employ relaxation. Sensitivity to distress cues is developed by activities such as keeping diaries on emotional experience, attending to areas of greatest tension during relaxation practice, and attending to arousal during in-session coping practice. Simultaneously, clients learn a basic relaxation response, usually through progressive relaxation training. As clients become proficient at relaxing, they learn ways to initiate relaxation quickly (e.g., relaxation without tension, cue-controlled

relaxation). Then they are provided in-session training in applying relaxation for emotional control. For example, anxious clients might visualize anxiety arousing situations, experience anxiety for 30 to 60 seconds, and then initiate relaxation to lower arousal.

During early therapy sessions anxiety arousal is mild to moderate, and therapists provide assistance in initiating relaxation. As clients experience success, the anxiety level is increased and the therapist assistance decreased so clients gain full self-control over their initiation of relaxation. Clients also practice the application of relaxation coping skills in external problem situations so they can employ relaxation whenever needed. Relaxation coping skills programs are effective with anxiety, fear, stress, anger, headaches, pain, and related forms of emotional discomfort.

Some clients' difficulties involve problems in assertiveness. Assertiveness requires an active, positive, expression of self, while respectfully entertaining and supporting the expression of others. Assertiveness is not a single behavior. For shy, inhibited individuals, assertiveness may mean giving voice to thoughts, feelings, and preferences; making reasonable requests of others; standing up for one's rights; setting interpersonal limits; expressing positive feelings toward others; and doing so without anxiety and reticence. For angry, aggressive individuals who express themselves but override and disrespect others, assertiveness may mean slowing down, not jumping to conclusions, actively listening to others, expressing themselves in calmer ways, sharing preferences without demand and intimidation, and respectful negotiation.

When assertiveness deficits and situations in which they occur are identified, therapist and client discuss appropriate behaviors for the situation. The therapist may model examples. Then, one or two aspects of the desired responding are specified (e.g., content of response, voice volume, or nonverbal behavior) and the client role-plays and rehearses those behaviors. The rehearsal is then debriefed; the client describes the experience, and the therapist reinforces and supports gains and clarifies remaining issues. The experience is repeated with attention to old and new behavioral elements.

Assertive behaviors are practiced in a natural setting with positive elements reinforced and troublesome behavior addressed in subsequent sessions. Over time, clients develop general principles and strategies of assertiveness and a flexible repertoire of assertive behaviors. Assertiveness training is effective

with timid, acquiescent individuals and with angry, aggressive individuals, and it is used in psychoeducational experiences for enhancing the well-being of nonclients.

*Modifying Consequences.* The law of effect draws attention to the fact that we can modify the consequences that follow behavior to develop desired behavior. Therapists, clients, and others can deliver consequences. Client and therapist can arrange for positive events to follow desired behavior (positive reinforcement). For example, parents might allow their youngster extra time with friends for expressing displeasure in a nonaggressive manner, or depressed clients might provide themselves with contingent amounts of video watching for initiating and engaging in social and physical activity.

Following a low-frequency but desired behavior with a higher-frequency, nonproblem behavior is also positively reinforcing. For example, a depressed person could follow a subvocal repetition of positive self-statements with a sip of coffee or tea.

Negative reinforcement (strengthening behavior by the reduction of negative outcomes) also can be employed. For example, a problem drinker might visualize starting to drink followed by an intense sensation of being about to vomit, and then visualize throwing the drink into the sink and experiencing relief of these aversive feelings. Initially, desired behaviors are reinforced every time they occur to maximize success. Over time, however, the frequency of reinforcement is reduced to make the behavior more likely to persist.

Punishment is another contingency that can be used to suppress behavior. For example, a man who ruminates obsessively about his ex-partner could self-administer a strong rubber band snap to decrease rumination. Punishment is used sparingly to prevent negative side effects. Where possible, removal of positive events is preferred over contingent presentation of painful stimuli. Every effort is made to combine punishment with the reinforcement of desired behavior. For example, smokers or alcoholics might visualize initiating problem consumption immediately followed by a noxious event such as vomiting (punishment). In other visualizations, they visualize initiating problem behavior, but stopping before consumption followed by a great sense of relief from not vomiting, thereby negatively reinforcing the desired behavior (i.e., resistance to temptation).

*Extinction* (not following a behavior with reinforcement) can reduce undesired behavior. One example is the use of exposure and response prevention in treating anxiety. Initially, certain situations elicit strong anxiety in the client, leading to dysfunctional avoidance and escape. These undesirable behaviors are strengthened by the negative reinforcement of anxiety reduction. To reverse this, clients are exposed to the cues that cause anxiety, but they are not allowed to avoid or escape, thereby preventing reinforcement of the undesirable behavior. With repetition, the association between the eliciting cues and anxiety is extinguished, as is the connection between anxiety and avoidance. Generally, exposure is gradual (i.e., it starts with low levels of anxiety and increases over time). Exposure and response prevention is often combined with interventions to enhance effective behavior. Exposure-based interventions are highly effective with phobic, panic, posttraumatic, and obsessive-compulsive issues.

### ***Flexible Structure***

Behavior therapy may not follow a regularly scheduled hour in the office. For example, exposure and response prevention and parenting skills training often require greater time. Intervention may take place in naturalistic settings (e.g., in a store with an unassertive client returning an item) or in simulated environments (e.g., in front of a camera for speech-anxious people). Behavior therapists employ homework and contracted tryouts outside counseling to extend and solidify clients' behaviors in their natural environments. Clients keep records of the assignments they complete outside the counseling sessions, and these are reviewed and used in planning further intervention efforts. Behavior therapists construct learning experiences to be efficacious, rather than limit them to an office hour.

### ***Maintenance and Relapse Prevention***

Behavior therapists expect difficulty in maintaining gains for many reasons. New behaviors are fragile and old behaviors are often highly reinforced. Environments and reinforcement contingencies shift. Times of stress may reinstate old conditions and reactions. Behavior therapists inform clients to expect slips and discuss maintenance and relapse prevention in the late stages of therapy. For example, conditions that often contribute to relapse are identified, and

strategies to minimize them are rehearsed. Clients may continue recording behaviors to keep a focus on maintenance. Therapists review records, reinforce maintenance, and troubleshoot problems. Later sessions might be scheduled further apart so clients have greater opportunity for relapse, which is addressed in subsequent sessions. Brief intervals of new counseling might be initiated to address relapse. Whatever the format, maintenance and relapse prevention are anticipated, normalized, and addressed.

### ***Client Readiness***

Behavior therapists expect resistance to change. Clients may not wish to give up reinforcement. Clients may have learned to externalize the source of behavior and blame others. Change may be avoided because it is associated with anxiety. Clients may not understand the nature of their issues, much less be ready to change. Such things lower client readiness for change.

When behavior therapists accept a client who is not yet ready for change, readiness for change becomes the initial focus of intervention. For example, rather than trying to convince angry, externalized clients to reduce their anger and aggression, behavior therapists might focus on an exploration of the consequences of client behavior. They could explore whether the clients are getting everything they want from their behavior or have their clients collect information from others regarding the impact of their behavior. Change may become the focus of therapy, but only when the clients are ready for change.

### ***Behavioral Groups***

Behavior therapy is often provided in groups. Groups are time limited, issue focused (e.g., anxiety reduction or assertiveness training), and sequentially structured to provide learning experiences that maximize success and minimize anxiety. For example, a group of unassertive, timid clients could be introduced to the notion of assertiveness and assisted in a series of graded steps to identify, rehearse, and employ assertive responding in daily life.

Behavioral groups offer the efficiency of group counseling and other benefits. Groups provide many different models and styles for behavioral rehearsal. Groups also provide different opinions about effective behavior, thereby leading to uniquely satisfying definitions of behavior for the individual. Modeling

effects may be enhanced by group work. In individual therapy, the therapist may be perceived as an expert, thereby making the gap between therapist and client too large for effective modeling. This problem is reduced in behavioral groups, because other group members serve as models during behavioral rehearsal. Other members also serve as powerful prompts for the desired behavior, and they can reinforce the desired behavior both within and between sessions (e.g., in a group of displaced workers, group members can call each other and support each other's job search behaviors). Behavioral groups can also occur in psychoeducational contexts in which nonclient participants are brought together to develop desired behaviors (e.g., stress or anger management).

### ***Behavioral Consultation***

Behavior therapists often consult with other professionals by conducting behavioral assessments and by designing and evaluating interventions. For example, behavior therapists might consult with school staff to design and implement interventions to diminish students' problem behavior. They might consult with nursing home staff to identify behavioral strategies that will increase client activity level and self-sufficiency and decrease depression. In this role, behavior therapists are a resource to the primary agents of change.

### ***Self-Directed Change***

Behavioral interventions can be highly self-directed. People may take classes on general principles of behavioral analysis and change or topic-specific classes (e.g., weight management or parenting skills). Instructors provide learning strategies and serve as consultants in the design and implementation of self-change projects. People may undertake self-directed change without professional assistance by using some of the detailed behavioral self-help materials that are available.

## **Other Therapy Issues**

### ***Therapeutic Relationship***

Behavior therapy regards the counseling relationship and alliance as very important, but not necessarily as the central factor in change. Clients may

withdraw from therapy if the behavior therapist is not a warm, supportive, empathic listener, because the client does not feel safe and trusting. A positive relationship allows clients to feel safe enough to reveal details about their lives from which collaborative conceptualization and intervention can be developed. Without a positive relationship, behavior therapists cannot conduct a thorough analysis of client concerns and clarify examples of critical antecedent-behavior-consequence sequences. Moreover, a positive relationship is very powerful in encouraging and reinforcing clients as they undertake new behaviors or take steps toward trying out anxiety-laden behaviors. For these reasons, the counseling relationship is considered a necessary condition for successful behavior therapy. The relationship supports and makes possible changes in environmental and learning conditions, which are the necessary conditions for lasting change.

### ***Attention to Emotion***

Behavior therapy is sensitive to feelings and emotions. Sometimes feelings (e.g., fear, depression, resentment, shame, and/or guilt) are primary issues and the target of intervention (e.g., anxiety or anger reduction). Learning to use a facilitative emotional tone is often an important part of a client's skill development. For example, emotional tone and paralinguistic characteristics are important elements of rehearsed behavior in assertiveness training (e.g., requests should be initiated in a calm, firm, respectful manner and compliments should be given with a positive voice inflection). Furthermore, behavior therapy may focus on behaviors and activities that increase positive emotions. Interventions may help clients scan for and take advantage of naturally occurring positive events or increase behaviors leading to positive feelings and a sense of mastery and self-efficacy.

Emotional reactions may be involved in another way. Clients are not likely to engage in new behavior that is culturally incongruent or generates conflict with their important attitudes and values (e.g., angry clients may initially be unwilling to try assertive behaviors because they interpret assertiveness as a sign of weakness or vulnerability). In behavior therapy such interpretations and feelings become the focus of intervention (e.g., helping clients understand how the behavior fits positively valued constructs and is therefore a sign of strength and self-empowerment).

Thus, behavior therapy is very emotionally focused, even if some of its language is not.

### **Insight**

Behavior therapy does not assume that deep cognitive and emotional exploration of family of origin or early traumatic issues is necessary for change. Behavior therapy may focus on earlier life issues to learn what they can teach about current problems and their maintenance and change. If the client's anxieties or dysfunctional behaviors are linked strongly to earlier issues, therapy may focus on these issues. The goal is not to provide insight, however, but to reduce anxiety and develop alternative, positive coping strategies. Behavior therapists do not believe that a deep understanding of earlier life issues is sufficient to affect a resolution of current concerns.

### **Cultural Sensitivity**

Behavior therapy is very sensitive to culture. In a general sense, culture is a broad set of norms, expectations, and sanctions for behavior. Behavior therapists assess these cultural norms and sanctions and make interventions consistent with the person's cultural experiences. Failure to do so would encourage clients' dysfunctional behavior and resistance to change, in addition to increasing the likelihood that clients will drop out of therapy. For example, relaxation interventions may be inconsistent with the beliefs of certain ethnic or religious groups. In a situation where the client belongs to such a group, a form of relaxation that fits with the client's cultural beliefs would be sought and integrated into therapy.

Culture may be a focus of behavioral intervention in at least two other ways. First, people may experience a cultural conflict where settings call for different behaviors (e.g., the client's culture of origin encourages deference to authority, whereas a current work environment encourages challenges to authority and an open, animated expression of ideas). Conflict, ambivalence, and avoidance may ensue. Therapy explores different cultural expectations and reinforcement structures and how to behave differently, yet comfortably, in different cultural contexts.

On other occasions, a change in culture may be considered. For example, delinquents and substance abusers often exist in subcultures that model and reinforce deviant, self-defeating behavior. Intervention

may focus on the client's changing environments, developing skills to resist reentering deviant environments, and developing new skills and reinforcement structures.

### **Conclusion**

Behavior therapy emphasizes the action-oriented psychological interventions based on learning theory that are most useful for clients who wish to change behaviors. The underlying premise of behavior therapy is that dysfunctional behaviors are learned and that clients can learn to discontinue those dysfunctional ways of behaving and substitute more effective ways of behaving in their place. Behavior therapy can be used by itself or integrated with other therapeutic approaches. An extensive body of research documents the effectiveness of behavior therapy.

## BIPOLAR DISORDER

---

Bipolar disorder (previously known as manic depression or manic depressive illness) is a psychiatric disorder marked by extreme shifts in mood from severe depression to mania (a highly activated state). The cyclical mood fluctuations that characterize this disorder can be devastating for the individual and family members and often result in significant impairment in social, interpersonal, and occupational functioning. Bipolar disorder is a serious illness that requires ongoing psychiatric and psychological treatment. Untreated individuals with bipolar disorder have a significantly higher lifetime rate of attempted suicide (25%) and completed suicide (10%–15%).

### Common Symptoms

The most severe form of the disorder, *bipolar I disorder*, is characterized by one or more manic or mixed (simultaneously manic and depressed) episodes of sufficient severity to cause marked impairment in social and occupational functioning, often resulting in a psychiatric hospitalization. Typically, people with bipolar I disorder experience extreme fluctuations in mood ranging from severe depression to mania. During manic episodes people experience euphoric, elevated, or irritable moods in which they may become highly energized, have an inflated sense of self-esteem, experience a reduced need for sleep, become very talkative, have racing thoughts, take on multiple projects at once, and become easily distracted.

People in a more severe state of mania may lose their normal sense of judgment and may undertake risky behaviors with the potential for painful negative consequences. In the most severe stages of acute mania individuals will become disorganized in their behavior and thought processes. These individuals may appear bizarre to others, and they may experience strange or unusual ideas.

*Bipolar II disorder* is distinguished from bipolar I disorder by the presence of a milder form of mania called hypomania. Hypomanic episodes are characterized by a shorter duration (4 days versus 7 days) than manic episodes and less severe impairment in social and occupational functioning. Hypomanic episodes do not terminate in grossly disorganized behavior or psychotic features that typically require hospitalization. While bipolar II disorder is often thought of as a

“milder form” of the disorder, individuals with this disorder have a high risk of suicide and a severe depressive course just as devastating as that experienced in bipolar I disorder. Individuals with bipolar II disorder may have significant interpersonal and occupational problems due to ongoing fluctuations in mood.

Individuals with bipolar I and bipolar II disorders also experience significant periods of depression. These periods are characterized by a depressed mood and loss of interest or pleasure as well as the following symptoms: significant weight loss or decrease or increase in appetite; sleeping too much or too little; and being agitated, slowed down, or feeling fatigued. During depressed periods, individuals often report feelings of worthlessness, excessive or inappropriate guilt, diminished ability to think or concentrate, indecisiveness, or suicidal thoughts or plans. A significantly elevated risk of suicide occurs during the depressed phase of bipolar and bipolar II.

The mildest form of bipolar disorder is cyclothymic disorder, a chronic fluctuating mood disorder characterized by numerous periods of hypomanic and depressive symptoms over at least 2 years. Individuals with cyclothymic disorder are at increased risk to develop bipolar I or bipolar II disorder.

### Age of Onset

The typical age of onset of bipolar disorder is at 20 years of age in both men and women. However, 50% of individuals experience an earlier onset (some as early as late childhood). About 10% of individuals experience a late-life (post-50) onset. Women are more at risk for depression (about 2 times the rate for men), but for bipolar disorder the gender ratio of male to female is about equal. There are no known differences in the rate of bipolar disorder in different ethnic groups or cultures.

In about 60% of cases, the disorder presents initially as a severe depression, but individuals may also experience an initial severe episode of mania. The symptoms of a severe bipolar I manic episode may include extreme agitation, disorganization, and psychotic features (hearing voices or believing in strange ideas). For the individual and family members, the onset of these symptoms can be extremely confusing and profoundly disturbing, especially if the young person has never before exhibited any significant problems. Diagnosis may be complicated because these symptoms overlap with signs of drug abuse and

schizophrenia, an illness also characterized chiefly by hearing voices (auditory hallucinations) and having strange ideas (delusions).

### Prevalence

The prevalence of bipolar I disorder is estimated to be between 1% and 1.2%, significantly lower than that of depression. However, taking into account both bipolar II (less severe mania) and other “less than manic” forms of the disorder, the overall prevalence rate of bipolar disorder may be closer to 4% to 5%.

### Etiology

Bipolar disorder is one of the psychiatric disorders known to have a very strong biological and genetic basis, substantially more so than depression. The probability of developing the disorder when a close biological relative has bipolar disorder is about 15% to 20% (i.e., 15–20 times the population risk). The probability is in the 50% to 70% range when both parents have the disorder. Environmental factors also play a significant role in the timing of the initial onset, the course of the disorder (as described below), and the prognosis of the disorder.

### Course and Prognosis

There is a great deal of variability in the course of bipolar disorder. About 90% of individuals who have an initial episode of mania have a second episode. In a high percentage of cases, manic episodes occur directly after a period of depression. Individuals may experience significant periods of wellness between episodes of mania and depression or, in many cases, may experience unremitting periods of continuing low-level depression. Approximately one third have residual symptoms that interfere with their social, interpersonal, and occupational functioning. Ongoing treatment, especially adherence to medication, greatly enhances quality of life and overall outcomes for these individuals.

### Assessment of Bipolar Disorder

The current prevailing scientific view of bipolar disorder conceives of the illness dimensionally rather than categorically. That is, bipolar disorder may be viewed as a part of a spectrum of disorders ranging from depression through cyclothymic disorder to

bipolar I disorder. This view has important implications for the assessment and treatment of the disorder in that the clinician must be alert to “less than manic” forms of the illness. Careful assessment before prescribing medication is important because people with bipolar disorder experience significant periods of depression as well as distinct periods of elevated mood. About 60% of people who present initially with mainly depressive symptoms may go on to experience a manic or hypomanic episode. People who receive an antidepressant may experience a medication-induced manic or hypomanic episode. While the severe symptoms associated with bipolar I disorder are easily recognized, milder forms of the illness can be easily overlooked with significantly negative consequences.

Assessment must always include a careful screening for past indications of either hypomania or mania with or without a history of depression. Longitudinal assessments rather than one-time assessments are preferred because of the episodic nature of the illness. Finally, because of the heritability of the illness, assessment should include a careful family history.

### Treatment of Bipolar Disorder

#### *Biological Treatment*

Treatment of bipolar disorder is complex and often involves several different classes of medication, including antidepressants, anticonvulsants, antipsychotics, and mood stabilizers. Lithium continues to be the gold standard for treatment, due to research that has been conducted confirming its long-term effectiveness.

Treatment can be divided into acute and maintenance phases. For acute mania or mixed states, a first-line treatment would be lithium, valproate, carbamazepine, haloperidol, aripiprazole, olanzapine, risperidone, or quetiapine. Any of these first-line treatments may be combined with adjunctive treatments that are intended to reduce symptoms of agitation, insomnia, or anxiety. For acute bipolar depression, a first-line treatment would be lamotrigine, olanzapine, or quetiapine. For individuals with rapid cycling (more than four mood episodes in 12 months), lamotrigine is the first-line choice. For maintenance with a mood stabilizer, lithium, valproate, lamotrigine, or aripiprazole may be considered. There is some debate as to the relative risk versus benefit of continuing treatment with antidepressants, which may in some cases exacerbate the illness.

Because of rapid changes in knowledge and practice in this area, the reader is cautioned that this discussion of biological treatment is not intended to substitute for professional medical consultation and advice.

Even the best pharmacological treatment rates are completely effective in less than 50% of patients. Significant problems with adherence to treatment (i.e., taking medication consistently as prescribed) greatly limit the overall effectiveness of medication-only approaches.

### **Psychotherapy or Psychosocial Treatment**

Some people are able to remain relatively stable on a long-term medication regimen. However, adjunctive psychotherapeutic treatment should be considered for individuals experiencing continuing episodes or significant periods of mood instability marked by breakthroughs of depression, mania, or hypomania. This is especially important if marked suicidal ideation, severe hopelessness, or mood instability is causing significant problems in an individual's living and quality of life.

Treatments that have demonstrated specific evidence of effectiveness include cognitive and cognitive-behavioral therapy, developed by Albert Ellis, Aaron Beck, and others, interpersonal and social rhythm therapy (IPSRT), developed by Ellen Frank; and family-focused treatment (FFT), developed by David Miklowitz. Effective treatments appear to share several common characteristics, including education about the disorder, emphasizing medication adherence, helping patients maintain lifestyle regularity, helping patients recognize early warning signs of illness, and helping patients develop specific coping plans in order to anticipate and minimize the impact of future episodes.

## **BRIEF THERAPY**

---

Brief therapy is a type of counseling that is time limited and present oriented. Brief therapy focuses on the client's presenting symptoms and current life circumstances, and it emphasizes the strengths and resources of the client. The therapist in brief therapy is active and directive. Termination of counseling is a major focus from the initial session.

### **History**

Brief therapy began to gain attention in the 1950s, following the increase in popularity of behavior therapy and family therapy. Behavior therapy emphasizes the correction of immediate problem behaviors and employs numerous behavioral techniques to facilitate change in the individual. Family therapy emphasizes the individual in the context of the family. In both therapies, the therapist is direct and active. These two therapies differ from earlier dominant therapies rooted in psychoanalytic thought that focus on the individual's insight and past, and in which the therapist is nondirective and passive. Thus behavior therapy and family therapy set the stage for the acceptance of active short-term therapeutic approaches.

The popularity of brief therapy increased in the 1980s, following empirical research on the process

and outcomes of psychotherapy. Researchers used meta-analysis, a statistical method allowing the results of many studies to be compared, to make the following conclusions about psychotherapy: (a) most clients stayed in therapy for six to eight sessions, (b) 75% of clients who reported improvement experienced benefits within the first 6 months of therapy, and (c) time-limited psychotherapy had outcomes similar to those of long-term therapy.

In addition to these research findings, societal changes increased the need and demand for brief therapy. Insurance companies, Health Maintenance Organizations (HMOs), and Preferred Provider Organization (PPOs) routinely place restrictions on the number of sessions an individual can attend. Some people, unwilling to go through insurance, elect to pay outright for their psychotherapy. Many individuals do not have the time or personal income for long-term therapy. Finally, the demand for therapy has increased while the supply of therapists (in the face of reduced fees and increased workloads) has decreased. Therefore, in many community and university counseling centers, there are not enough therapists to see clients for long-term courses of therapy. Brief therapy has become an attractive method for meeting the increased demand for counseling services in a way that is timely and cost-efficient.

## Types

There are many approaches to brief therapy. Typically, existing long-term therapies have been adapted to a short-term context. Table 1 below provides a list of the most popular approaches followed by key concepts and suggested readings for each type of therapy.

### ***Single-Session Therapy***

#### **Theory of Single-Session Therapy**

In single-session therapy, the therapist and client meet only once. The goal of single-session therapy is to encourage new learning, enhance coping, and promote growth. Typically, a single session is used to help a client shift perspective or acquire skills. Single-session therapy is most effective for individuals with specific problems who (a) need a change in perspective, (b) need an evaluation or referral, (c) feel stuck about processing a past event, (d) are looking for reassurance, or (e) have a specific problem that is within

their power to solve. In contrast, individuals in inpatient care, individuals needing continuing support to process traumatic past events (e.g., childhood sexual abuse), individuals with eating disorders or chronic pain, and individuals with conditions caused by biological or chemical mechanisms (e.g., schizophrenia) are not as likely to benefit from single-session therapy or any of the brief therapies.

#### **Techniques of Single-Session Therapy**

Diverse techniques are employed in single-session therapy. For example, the therapist may contact the client by phone before meeting to obtain detailed information about the presenting problem and to ask the client to complete specific tasks before the session. A second popular technique is to focus on ambiguity during the session. Focusing on ambiguity allows the therapist to introduce new ways of looking at the same problem. Clients often practice possible solutions during the session. Rehearsing ideal outcomes or practicing new skills can help a client feel more able to transfer skills from the therapy session to everyday life. After the session is over, the therapist informs the client that he or she can return for another session if necessary.

### ***Cognitive-Behavioral Brief Therapy***

#### **Theory of Cognitive-Behavioral Brief Therapy**

Cognitive-behavioral brief therapy focuses on schemas. *Schemas* are templates that individuals use in order to make decisions, guide responses, or explain situations. Schemas develop from life experiences and become a standard of normal behavior. Thus, whenever a critical event occurs, the individual uses a schema to decide how to react. Schemas may not be based on accurate information, so relying on some schemas may result in cognitive distortions. For example, if a child were punished whenever interrupting an adult, that child may develop beliefs that make him or her hesitant to interrupt, even as an adult.

#### **Techniques of Cognitive-Behavioral Brief Therapy**

The focus in cognitive-behavioral brief therapy is to identify and replace distorted cognitions based on schemas. Goal setting is central to cognitive-behavioral

**Table 1** Summary of types of brief therapy

<i>Type of Therapy</i>	<i>Key Concepts</i>	<i>Suggested Readings</i>
Adlerian	Roots behavior in socially-constructed meaning Focuses on who the client is and what the client wants Shifts the underlying rules of interactions	Bitter & Nicoll (2004)
Cognitive-behavioral	Identifies and replaces the client's distorted cognitions Sets goals with specific objectives Emphasizes measuring treatment effectiveness	Dziegielewski (1997)
Depth-oriented	Uncovers the hidden emotional meaning behind issues Actively engages emotional, cognitive, somatic, behavioral, and unconscious aspects	Ecker & Hulley (1996)
Eclectic	Posits that no theory can work all the time with all clients Combines several theories and uses many techniques Focuses on optimism, enhancing coping skills, adapting to change	Wells (1994)
Ecosystemic	Focuses on social systems, strengths, and persuasion Emphasizes small changes that lead to larger systemic changes Maps social systems and behavior patterns	Miller (1997)
Family	Focuses on family system issue instead of individual problem Uses intermittent sessions and one-way mirror team Has clients rate the problem on a scale from "worst it's ever been" to "best I can imagine"; increases awareness of small improvements	Kisch (1997)
Gestalt	Focuses on fragmentation and reintegration of the self Stresses the importance of nonverbal behavior Uses the empty-chair technique	Williams (2001)
Group	Recreates patterns of client interpersonal difficulties in the group Allows the client to practice new behaviors, with group members giving feedback Focuses on task assignment and problem solving	Garvin (1990)
Interpersonal	Explores interpersonal problems to identify issues Uses client-therapist relationship as a tool Connects stressful events with client's current mood	Dziegielewski (1997)
Marital	Stresses conflict resolution and communication strategies Employs I-messages, active listening, and borrowing client's voice Examines intergenerational context of learning	Magnuson & Norem (1998)
Short-term dynamic	Explores the internal phobia of experiencing a specific feeling Utilizes triangle of conflict and triangle of person Restructures defenses, affect, and attachments	McCullough & Osborn (2004)
Single session	Includes presession contact Focuses on ambiguities Has clients practice skills in session	Hoyt (1995)

brief therapy. It serves as a mechanism for measuring treatment effectiveness. Each goal should have specific objectives, be worded positively, and be realistic. Cognitive-behavioral brief therapy focuses on meeting each goal, as opposed to focusing on client insight or the process of therapy.

### **Short-Term Dynamic Psychotherapy**

#### **Theory of Short-Term Dynamic Psychotherapy**

Short-term dynamic psychotherapy focuses on affect phobia. *Affect phobia* is an internal phobia in which individuals are afraid to experience a particular feeling (e.g., anger, shame). According to short-term dynamic theory, affect is the basic motivation that drives individuals, and affect phobias are the culprit of most behavior problems.

Triangles are used to diagram conflicts and people in short-term dynamic psychotherapy. The *triangle of conflict* is used to conceptualize the way an individual avoids a feeling and the *triangle of person* is used to conceptualize the recipient of that feeling. The triangle of conflict uncovers defenses, anxieties, and adaptive feelings. Each point on a triangle is called a *pole*. The *defense pole* consists of behaviors (e.g., avoidance), thoughts (e.g., “I’m incompetent”), or feelings (e.g., fear). These defenses can be adaptive and helpful, but they become harmful when they result in maladaptive behaviors. The *anxiety pole* consists of inhibitory feelings that lead individuals to become vigilant about their own or others’ behaviors. There are four major categories of inhibitory feelings: anxiety, shame/guilt, emotional pain, and contempt/disgust. The *feelings pole* represents normal adaptive behaviors that are motivated by underlying basic feelings and impulses (e.g., grief, anger, excitement, sexual desire). These feelings can be healthy, but individuals avoid them when the feelings are associated with a negative experience. The triangle of conflict helps the therapist to identify defensive patterns used by the client to avoid feelings, identify how and why a client is using inhibitory feelings, and help the client understand the underlying affect that is being avoided.

The triangle of person helps the therapist recognize the relationships where patterns of avoidance occur. These can include past relationships, current relationships, or the relationship between the client and therapist.

#### **Techniques of Short-Term Dynamic Psychotherapy**

The goal of short-term dynamic psychotherapy is to restructure defenses, affect, and attachments. There are several main objectives. First, the client should acknowledge and understand the defensive pattern. Second, the client should be motivated to change the defensive pattern. Third, in order to desensitize the affect phobia, the client must experience and express appropriate feelings. Fourth, the therapist must listen to the client and help identify healthy feelings that can help the client to behave more effectively and experience relief from his or her symptoms.

### **Gestalt Brief Therapy**

#### **Theory of Gestalt Brief Therapy**

From a Gestalt perspective, individuals are experiencing difficulty because they have become fragmented by disowning different parts of themselves. Therefore, the aim of Gestalt brief therapy is to reintegrate the fragmented parts of the individual. Once the reintegration process has occurred, the individual can successfully interact with him- or herself, others, and the environment. In Gestalt brief therapy, the focus is on growth and process. Nonverbal cues are a key part of Gestalt brief therapy. In fact, if the verbal content of the client is in conflict with the nonverbal content of the client, the nonverbal content is usually considered more important. For example, if a client reports feeling relaxed but fidgets constantly, then the therapist would assume that the client is not relaxed. The therapist may also point out this incongruence during the session.

#### **Techniques of Gestalt Brief Therapy**

Gestalt brief therapy uses Duey Freeman’s therapeutic circle as a guide for brief therapy. There are six stages in Gestalt brief therapy. First, therapy must begin with a present or here-and-now focus. Gestalt brief therapy helps the client to increase awareness of immediate feelings, experiences, and situations. Second, an issue is identified. The therapist does not direct the client to identify a particular issue. Instead, the therapist simply helps the client increase awareness of the here and now, and trusts the client to talk about an issue that is important.

Third, the therapist may conduct an “experiment” during the session. Gestalt therapy considers techniques

to be experiments. For example, the therapist may make a client aware of nonverbal cues throughout the session. Perhaps the most popular experiment is the empty chair technique. In this experiment, a client is asked to initiate a dialogue between the two parts of the self that are in conflict, or with another person with whom the client is experiencing conflict. Each time the client switches perspectives, the client switches chairs and talks to an empty chair as if the other part of the self or the other person were in the chair.

Fourth, the therapist identifies and discusses the behavior that is causing the problem. This moves the discussion from the present to the past, but in Gestalt brief therapy, the past is discussed in the context of how the client is currently experiencing issues from the past in the present. Therefore, the emphasis is not on discussing the past, but experiencing the past. Fifth, the client and therapist explore alternative behaviors. These alternate behaviors may be external or internal. Sixth, the therapist and client discuss how life is different when trying these alternate behaviors. The therapist assists the client in the integration of these new behaviors into daily life.

### Future Directions

The increase in cost-conscious managed medical care (i.e., HMOs, PPOs) and the need to deliver services to a growing population suggest that therapists will continue to be interested in brief therapy. As brief therapy increases in popularity, therapists will become more highly trained in brief therapy and research will be conducted that will better demonstrate which brief therapies are the most effective for which psychological problems. Importantly, there are some instances in which longer-term therapy will be more beneficial (e.g., treatment of severe traumas, eating disorders, personality disorders, schizophrenia). In general, though, brief therapy is cost effective and efficacious.

## CLIENT ATTITUDES AND BEHAVIORS

---

The therapeutic process holds both majesty and mystery for its participants. Client knowledge about the process ranges from total unfamiliarity with and/or misinformation about therapy—and what to expect of it—to the unique sophistication of the client who has entered into episodic therapy with several therapists. Given that individuals bring the sum of their past experiences as well as their current state into the therapeutic process, it is appropriate to assume that client expectations, behaviors, and outcomes vary due to these and many other factors, such as temperament, early learning about relationships, capacity to trust, experience of trauma, current stress level, and cultural mores.

How, then, do therapists proceed to create a therapeutic alliance that allows the maximum gain for their clients? What client attitudes and behaviors mediate the outcome of successful therapy? How does the therapist accommodate these issues when inviting a relationship, determining a course of therapeutic action, or approaching a problem area? The American Psychological Association Division 29 Task Force on Empirically Supported Therapy Relationships has compiled information on client characteristics within the therapy relationship that have been shown to enhance therapeutic outcome. This entry addresses some of these factors.

### Meaning-Making and Attribution

The term *first impression* generally denotes an individual's immediate sense and understanding of an

encounter with a specific person or situation. Individuals may use many different pieces of information as evidence for making quick judgments about others that may become lasting beliefs. Researchers have suggested that humans have a unique ability to judge personality traits and complex social characteristics—such as dominance, hierarchy, warmth, fear, and threat—from their first impression of individuals they meet or see in a photograph.

The client's assessment of the personal character of the therapist, including the therapist's physical appearance and dress, professional reputation, assumed ethnicity, and gender, is influenced by the innumerable experiences the client has synthesized over his or her lifetime. Such impressions often lead to permanent judgments and emotional reactions to others, particularly those perceived to be in positions of authority or power. There is little a therapist can do to change clients' past experiences and how these experiences affect their relationships to the therapist and the experience of counseling. Therapists accept that some issues may be projected onto the therapist and create a distorted view of the interactions between client and therapist. Therapists then work to provide a way in which clients may be able to recognize their distortions when the distortions are pointed out by the therapist in a respectful, well-timed, and appropriate manner.

Different schools of therapy have different labels for these projective phenomena: transference and countertransference, products of early learning, personal schemas, or projective identification. The client's attribution of specific positive and negative qualities to the therapist and therapeutic process allows the therapist to understand how the client

views the world and to provide corrective emotional experiences through addressing the appropriateness and validity of the client's ascriptions. It also provides a platform for therapists to evaluate themselves and their own attributions and biases through self-reflection, supervision, or their own psychotherapy.

Clients may reenact in therapy their prior experiences in order to determine if there is truth to their beliefs or to verify that their past course of action was valid. Examples of this are clients who continually check that their therapists have scheduled the standing appointment that has been attended for months or those who will tell their therapists about others who have committed an error and then intently gauge their therapists' reactions in order to see how faults and/or past behavior may be accepted. Obviously, therapists' attention to language and the meanings of verbal and nonverbal interactions are essential for a positive therapeutic outcome.

Once therapists sense the distortions and biases of the client, they may modify their own behavior and dialogue in unique and distinctive ways. The ability to engage in conscious self-regulation varies among therapists and in different situations; clients appear to have inconsistent levels of awareness of personal schemas, scripts, value systems, cultural biases, and clinical expectations as well. An awareness of habitual ways of interpreting personal information is one of the significant benefits clients may derive from therapy. What appeared to the client to be an adaptive response to a prior problematic situation may now be seen as an irrational action or thought that is within the client's control to change if necessary.

### **Therapeutic Relationship**

Adam Horvath emphasized that a client's first impression and early therapeutic alliance or relationship may predict the outcome of psychotherapy. The therapeutic relationship is conceptualized as the quality and strength of the collaborative relationship between client and therapist in therapy and the positive affective bonds between client and therapist—mutual trust, liking, respect, and caring. It also includes the active establishment of and allegiance to the goals of therapy and the means by which these goals will be attained. The therapeutic alliance creates a sense of shared responsibility in therapy in which each participant is actively committed to his or her specific responsibilities in therapy, and

believes the other is equally committed to and invested in the process.

Clara Hill envisioned the therapeutic relationship as evolving over time as the result of the intersection of therapist techniques and client involvement. The therapist is able to employ theoretically appropriate techniques that lead to more intense client engagement and increasing therapist influence, strengthening the therapeutic relationship as it changes during the course of therapy. She viewed supportive and engaging therapist techniques as venues that permit the client to become involved in the therapy process.

### **Empathy**

Empathy is defined as the therapist's perceptive and sensitive ability and willingness to understand the client's thoughts, feelings, and struggles from the client's point of view. In a meta-analysis of empathy and psychotherapy outcome conducted by Leslie Greenberg, Jeanne Watson, Robert Elliott, and Arthur Bohart, four theoretical factors were identified as potential mediators linking empathy and therapeutic outcome. Three of the factors comprise the processes of empathy as a relationship condition, as a corrective emotional experience, and as a cognitive-affective processing condition. The fourth factor is associated with the role of the client as an active self-healer.

Relationally, empathy provides a positive bonding function. Empathy (i.e., feeling understood) increases client satisfaction with therapy and thereby increases compliance with therapist suggestions and/or homework (most often utilized in cognitive-behavioral therapy). Feeling understood has been related to increased feelings of safety in the relationship and comfort when self-disclosure occurred. In addition, clients who felt understood also felt safer when approaching difficult topic areas and appeared to stay longer in therapy rather than prematurely terminating it. Empathy offers a specific learning or corrective emotional or relational experience. Hypothetically, an empathic relationship may help strengthen the self, diminish isolation, and facilitate clients' experiences of personal value, including the possibility that they are worthy of respect and of being attended to and heard. Perceived empathy may validate the veracity of clients' feelings and behaviors. This empathic reflection and validation might eventually lead clients' to develop the ability to express their feelings and needs in relationships. Empathy may also promote exploration and creation of meaning. It helps

clients think more productively, raises levels of constructive experiencing, facilitates emotional reprocessing and decreases emotional angst due to anxiety and depression, as well as providing learning experiences.

Arthur Bohart and Karen Tallman suggested that therapy works fundamentally by supporting and encouraging clients' active self-healing efforts. Clients are seen as having innate capacities for growth and change, and therapy becomes the educational process that helps clients mobilize their resources. The therapist's empathy contributes to this process by furthering client involvement and openness to the process. In addition, it provides an "empathic workspace" where clients can draw on their capacities for self-healing. This perspective of client as "self-healer" differs from more medical views of psychotherapy wherein the therapist is viewed as the expert healer.

### Deference

Deference is commonly defined as individuals' submission of thoughts, opinion, and projected course of action to another person, who is recognized as superior in knowledge, skill, judgment, and so forth. In the therapy dyad, the therapist is generally considered more expert than the client—a situation that could be expected to exacerbate the client's deference to perceived therapist directives. This phenomenon has been overlooked in the literature on the counseling relationship. David Rennie noted that attention has been directed more to concepts presumed to relate to the process of improvement in therapy, particularly transference, resistance, empowerment, and the working alliance. Rennie postulated that clients' deference to the therapist consists of eight categories: concern about the therapist's approach, fear of criticizing the therapist, understanding the therapist's frame of reference, meeting the perceived expectations of the therapist, accepting the therapist's limitations, client's metacommunication, threatening the therapist's self-esteem, and indebtedness to the therapist.

The most direct effect of clients' deference appears to be on the establishment of a positive working alliance and, in a tangential way, the client's resistance. Being deferential to the therapist is seen as the client's way of protecting and fostering the alliance. However, deference may at times be costly for clients, sapping their energy and thereby creating difficulty with their commitment to the therapist's strategies and expectations. Nonetheless, whether clients would

appreciate a request to express dissatisfaction may be determined by the degree to which the discontent disturbs the clients' ability to focus constructively on their own processes. The awareness that many clients are extremely disposed to be deferential might increase therapists' awareness and influence their clinical judgment, and help them avoid the conflict that comes from a client's inner feelings of not being good enough, smart enough, or worthy of positive outcomes.

### Stages of Change

In the transtheoretical model of therapeutic change developed by James O. Prochaska and John Norcross, behavior change is seen as a process that unfolds over time and involves movement through a series of six stages: precontemplation, contemplation, preparation, action, maintenance, and termination. Each stage represents a period of time and a series of tasks that must be completed before movement to the next stage is possible. Although the amount of time an individual spends in each stage will vary, the tasks to be accomplished during each stage are assumed to be the same. The stages of change model provides a way of thinking about client readiness to change.

In the *precontemplation* stage, individuals do not intend to change their behavior in the near future. Most individuals in this stage are unaware or under-aware of their problems, although their intimates—family, friends, neighbors, and coworkers—are often aware of the precontemplator's problems. When precontemplators present for psychotherapy, they are likely to do so because of pressure from others. Precontemplators can wish or hope to change, but do not seriously intend or earnestly consider changing.

*Contemplation* is the stage where individuals are aware that a problem exists and are sincerely thinking about overcoming it, but have not yet committed to a course of action. Individuals often are in this stage for long periods of time. Those who state that they are seriously considering changing the problem behavior in the next 6 months are classified as contemplators. The *preparation* stage combines intention and behavioral criteria. Individuals in this stage intend to take action in the next month or so, as their past actions surrounding change have not been successful. Individuals in this stage have experienced a slight decrease in their problem, but have not yet reached a level of effective action such as the absence of anger or a decrease in their symptoms of anxiety.

During the *action* stage individuals transform their behavior, experiences, and environment in order to surmount their problems. Action involves explicit behavioral changes and requires a serious commitment of time and energy. Modifications of the problem behavior occurring during the action stage tend to be readily visible. Individuals are classified as in the action stage if they have successfully changed or seriously modified the dysfunctional behavior for a period from 1 day to 6 months.

*Maintenance* is the stage where individuals work to prevent relapse and consolidate their current gains. Remaining free of the problem behavior and consistently engaging in a positive incompatible behavior for more than 6 months are the criteria for considering someone to be in the maintenance stage. The final stage is termination. *Termination* means that individuals have completed the change process and no longer have to work consciously to prevent relapse. Termination is defined as total confidence or self-efficacy across all high-risk situations and no temptation to relapse.

At each stage of change, different processes of change generate progress. Formulating change processes to facilitate optimal change within the different stages necessitates that the therapeutic relationship correspond to the client's stage of change. As clients progress from one stage to the next, the therapeutic relationship also progresses. There is an increasing body of research evidence on how tailoring the therapy relationship to the stage of change can enhance outcome, since the various change processes are not equally effective in each stage of change.

The research by Prochaska and Norcross noted that therapists who tailored their interventions to the client's stage had clients with an increased completion rate for a course of therapy and who continued to implement and maintain change. Prochaska and Norcross's work suggested that change processes associated with experiential, cognitive, and psychoanalytic orientations appear to be most valuable during the earlier precontemplation and contemplation stages. Change processes traditionally associated with the existential and behavioral traditions, by contrast, are most useful during action and maintenance. Prochaska and Norcross recommended that therapists consider the following:

- Assess the client's stage of change; tailor therapy relationships and interventions accordingly.
- Beware of treating all clients as though they are in an action phase, as the majority of clients are not. An

estimated 10% to 20% are prepared for action, about 30% to 40% are in the contemplation stage, and 50% to 60% in the precontemplation stage.

- Set realistic goals; move one stage at a time and celebrate success as appropriate for the current stage. Helping clients move beyond the stuck phase of precontemplation is a therapeutic success. This likely doubles the chances of clients taking effective action in the next 6 months.
- Engage in interpersonal behaviors that tailor the therapeutic relationship to the client's change stage and use techniques that are consistent with the change processes that are most effective at that stage.
- Avoid mismatching stages and processes. Modifying behavior without awareness of the client's stage of change and prescribing overt action without insight into the change process and the client's stage most often engenders only temporary change.

## Self-Disclosure

Talking to others about difficult parts of themselves is a challenge for most individuals; nevertheless, it is important within the therapeutic relationship for clients to allow their therapist to know the hidden, misunderstood, even shameful parts of themselves. In general, research has shown that clients who are in moderate to long-term psychotherapy state that they view therapy as a safe place to disclose, particularly if they perceive the therapeutic relationship as good. For the most part, active participants in psychotherapy describe the disclosure process as principally generating shame and anxiety at the outset, but eventually as evoking feelings of safety, pride, and genuineness. They also note that keeping secrets inhibits their progress in therapy and disclosing produces a sense of liberation from physical and emotional tension. It is generally held that initial disclosures in therapy smooth the progress of subsequent disclosures to clients' family members and friends and the continued disclosure of difficult parts of themselves to their therapist. The consensus is that therapists should gently pursue material that is difficult to disclose.

It should be noted that therapists' self-disclosures to their clients might engender positive or negative results. The sharing of the therapists' personal and private experiences must be in the service of client understanding and comfort rather than for the therapists' self-aggrandizement. When the focus remains on the client and the disclosures (often in the form of stories)

remain pertinent to the issues at hand, they usually have positive effects in therapy, frequently helping clients feel understood and allowing clients to move on to other significant issues. When clients' issues are not addressed, however, a breach in the relationship occurs and may lead to negative outcomes such as premature termination or clients testing the relationship through various modes, which may include missing appointments or failing to invest in positive change.

Clients' reactions to therapist disclosure have been studied in laboratory settings using videotapes of client-therapist interaction. Research has shown that as long as the therapeutic alliance was positive, study participants rated sessions as more meaningful and the therapist as more expert when the therapist made general disclosures versus no disclosures at all. When the alliance was negative, clients rated the sessions where therapist disclosure occurred as more superficial and the therapist as less skilled when the therapist made either general or countertransference disclosures as opposed to no disclosures.

There are a number of factors that influence clients' willingness to disclose. The research of Barry Farber, Kathryn Berano, and Joseph Capobianco indicated that about half of clients keep secrets from their therapists. This occurs mostly in the areas of relationship issues, sexual problems, and perceived personal failures. The subjects of clients' parents and despised personal characteristics are the topics most addressed within the therapy session. Women and men seem to disclose equally. The longer a client is in therapy and the stronger the clients consider their therapeutic alliance, the more willing clients are to disclose to their therapist.

### Client Self-Observation as a Precursor to Change

The activation of self-observation is a collaborative feature of all psychotherapies. It differs from self-awareness and relies upon consciousness to provide context and reality. Self-awareness is the capacity to know one's self and one's self-in-context. Self-observation is the act of examining one's inner landscape (intentions, expectations, emotions, thoughts, and behaviors), processing this information, and exploring the ideas in other people's minds, as well as what others think of the self.

Clients become aware of and learn about their own functioning in order to change maladaptive responses and generate new responses for the future. In helping

clients focus attention on their own distinctive patterns, psychotherapists assist clients in activating their self-observation. This process is an implicit and multifaceted thread that runs through the different psychotherapies. It gives the client permanent tools to use during the process of change that is the object of psychotherapy.

## CLINICAL INTERVIEW AS AN ASSESSMENT TECHNIQUE

---

A clinical interview involves counselors asking individuals questions to gather pertinent information. In interviewing, therapists attempt to help individuals feel comfortable so that candid and relevant information is revealed. Clinical interviewing occurs throughout the counseling process but is typically a major component of the initial session.

An initial interview focuses on gathering information. Therapists generally gather demographic information (e.g., marital status, race or ethnicity, and employment) and information about current problems (e.g., frequency of problem, degree problem affects functioning, and previous attempts to solve problems). Additional questions are asked about social support, medical history, and current medications. Furthermore, therapists may ask questions regarding suicide, substance use, and issues of violence. The information gathered during the initial clinical interview influences the treatment plan, so honest communication is essential to permit accurate assessment.

The initial interview and other interviewing assessments conducted during the counseling process can be useful in assessing client issues. The effectiveness of clinical interviewing is more dependent on counselors' communication skills than are more formal assessment techniques. Depending on the type of information sought, therapists may use formal assessments and behavioral observations to supplement the clinical

interview. These techniques help gather information in a systematic manner; however, many counselors believe there is no substitute for the wealth of information typically gained during the clinical interview.

### Types of Clinical Interviews

There are three types of clinical interviews: structured, unstructured, and semistructured. The type of interview used varies according to the setting and the theoretical or professional orientation of the therapist. A *structured interview* requires that the same questions be asked of each client in an identical manner. An *unstructured interview* allows the counselor to determine the questions and topics covered during the interview. A *semistructured interview* combines these formats. Specific questions are always asked, but these are coupled with opportunities to explore unique client circumstances.

There are advantages and disadvantages to each interview format. The questions asked in a structured interview have been researched to determine if they are reliable and whether they elicit useful and valid information. Consequently, the structured interview provides more consistent information. However, a structured interview may not be appropriate for clients with less common problems or clients from diverse cultures. Although the unstructured interview can be adjusted for individual clients, its effectiveness depends on the clinician's interviewing skills and ability to interpret the clients' answers.

Commonly used structured interviews are the Composite International Diagnostic Interviews: Authorized Core Version 1.0 (CIDI-CORE) and the Diagnostic Interview Schedule (DIS). Some typical semistructured interviews are the Psychiatric Research Interview for Substance and Mental Disorders (PRISM) and the Structured Clinical Interview for Axis I DSM-IV Disorders (SCID-I).

### Interviewing Techniques

Effective clinicians exhibit interpersonal warmth, refined skills, and attentiveness. They use open-ended questions that allow clients to elaborate on their thoughts and feelings and answer questions in "their own words." An example of a closed-ended question is, "Do you drink alcohol?" whereas an open-ended question might be, "Why don't you tell me about your drinking?"

The clinical interviewing process as an assessment technique continues well after the first session. Clinical interviewing also is used to monitor problem resolution, interpersonal development, daily functioning, and client progress. Clinical interviewing may also be used to evaluate the counseling process by asking clients questions concerning the degree to which counseling was helpful.

## CLINICAL PRESENTING ISSUES

---

The *presenting issue* is the brief description clients use to describe their reasons for seeking help when seeking psychological services. It is the initial clue encountered by psychologists in their efforts to help clients solve the problems that have brought them to therapy. The presenting issue may be complete and focused on the primary issue of concern to the client, vague and largely unrelated to the most pressing concerns of the client, or somewhere in between those extremes. This imperfect relation between the presenting issue and the focal issues upon which the client and psychologist will eventually work is reflected in the common clinical adage: "The career counseling referral is always a psychotherapy referral, and a psychotherapy referral is always a career counseling referral." Therefore, the presenting issue is best regarded as the opening statement in a dialogue between the psychologist and the person seeking help rather than as a statement of fact. As such, psychologists must give it their close attention and treat it with the respect it deserves while

understanding that it does not necessarily tell the entire story. Presenting issues tend to vary as a function of the helping professional being addressed (e.g., psychologist, counselor, psychiatrist, clinical social worker, or vocational counselor), the setting in which services are sought (e.g., college counseling center, community mental health center, or hospital), and the client's characteristics (e.g., mandated client or child, teen, or adult voluntarily seeking services). This entry reviews the presenting issues prominent in each of these.

### Helping Professional

The theoretical and empirical contributions of Stanley Strong, Charlie Gelso, and Howard E. A. Tinsley have been instrumental in demonstrating the influence of the helping professional on the presenting problem. The name by which the "helper" is known influences the likelihood an individual will seek assistance from that person. The typical individual is more likely to seek help for personal problems involving a spouse, family member, or member of the opposite sex from a counseling psychologist. Psychiatrists, clinical psychologists, and peer counselors are less likely to be seen by persons with those presenting problems. Psychiatrists and counseling psychologists are most likely to be seen by individuals who are troubled by thoughts of suicide or concern about their emotional stability. People who desire help with career plans, problems on the job, or developing a life plan are most likely to seek the assistance of a career counselor, a college counselor, a close friend, or a relative. In general, therefore, people tend to have a general idea of the relative areas of expertise offered by the different potential helpers and to base their help-seeking decisions on those beliefs.

Although this is a sound, common-sense approach, people seeking help do not always understand (or may not be ready to admit) the true nature of their concerns. For this reason, helping professionals must be broadly trained and stand ready to refer clients when they conclude that another helper is better prepared to help the client.

Clients are in a state of vulnerability or even crisis at the time they are stating their presenting problem. For this reason, Randolph Pipes and Donna Davenport have underscored the importance of therapist sensitivity and competence in crisis management. Skilled therapists understand that in addition to the pain caused by their personal situation, clients typically experience some trepidation about disclosing the

relevant personal information to a therapist (and many clients are troubled by the nagging doubt that no one—and especially not the therapist they do not yet know—could understand what they are experiencing.

A substantial number of clients do not return after their first interview with a therapist. For this reason, experiencing and communicating respect for clients and their experiences is a key therapeutic factor when considering the referral problem. Although that may sound like a fundamental social skill, skilled psychologists understand that respect is deeply embedded in a cultural context. Multicultural competency is critical clinical skill expected of therapists, and psychologists are called upon to exercise this competency from the clinician's first reading of a phone message to their more formal assessment of the reason for referral.

### Setting

The most systematic body of research on presenting issues has been conducted in university counseling centers. The evidence, of course, tends to yield answers that are somewhat typical of individuals at that developmental stage. Concerns about personal values, academic and emotional stress, body image, alcohol use, and adjustment to college life tend to be salient presenting issues on college campuses. For female students the 10 most distressing concerns, ranked in terms of their severity, are anxiety and worry, academic concerns, depression, stress management, concern about the future, self-esteem and self-confidence, procrastination and motivation, career and college major selection, finances, and concentration. In contrast to popular stereotypes of the college years, loss of relationships and dating concerns ranked relatively low. For males the same 10 problems were ranked as their most severe presenting concerns, but the order was slightly different. The men ranked concentration, procrastination, and motivation as more troublesome than the women did, and stress management, self-esteem, and self-confidence as less troublesome.

A different picture emerges from clients seeking services from the department of psychiatry in a university medical center. Their most frequent presenting issues involved mood disorders, substance abuse, anxiety disorders, psychotic disorders, and eating disorders.

Community mental health centers often see the broadest range of presenting problems, since these centers tend to be both the initial point of contact for the community, particularly those with few resources,

and the safety net or service provider of last resort. As a result, community mental health centers deal with mental health matters ranging from the crises of suicidal behavior to the chronic problems of schizophrenia and bipolar disorder.

### Help Seekers

#### *Children and Adolescents*

In general, parents initiate mental health services for their children. However, the agreement between parent and child identifications of the presenting problem is quite low. In one recent study more than 60% of the parent-child pairs failed to agree on a single problem for which the child needed help. Even when the presenting issues were grouped into broad categories, more than a third of the parent-child pairs failed to agree on even one general area in which the child needed help. It appears that parents and children see the presenting problems quite differently.

Parents and children are in better agreement regarding the child's need for help with externalizing behaviors than their need for help with internalizing behaviors. Externalizing behaviors such as fighting, arguing, and disruptive behaviors are readily observable, so it is not surprising that parents are more aware of the child's needs in this regard. In contrast, internalizing behaviors such as anxiety, depression, and low self-esteem are more subjective. It is more difficult for parents to become aware of the child's need for help with these issues, and their awareness of the child's needs is dependent in large part on the child's willingness to express these needs to his or her parents. It is also true that parents and children are in better agreement regarding the problems that bother the child than they are the problems that bother the parents. This is most likely due to the parents' decision to avoid burdening the child with knowledge of the stress and anxiety the child's problems are causing the parents.

A recent Surgeon General's Report on Mental Health stated that during the course of a year, one in five children and adolescents manifest the signs and symptoms of a disorder found in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*, and about 5% of all children experience an "extreme functional impairment." This estimate is consistent with the 2001 finding of the Policy Leadership Cadre for Mental Health in Schools

that more than 20% of the primary healthcare visits of children are prompted by mental health concerns.

A different perspective emerges from a large survey of regular and special education teachers, school counselors, and school psychologists who were asked to rate the severity of 10 presenting emotional/behavioral problems in their school. Impaired self-esteem was rated as the most serious problem. Suicidal thoughts or behaviors and inappropriate sexual behavior were generally rated as being of least concern. However, these findings may speak more to the prevalence and amenability to observation of adolescents' problems than to their severity. School personnel may be quite aware of the troublesome nature of common and observable problems. More severe problems may be more rare and not as readily observable (internalized). For example, even highly trained specialists are not able to predict with any degree of accuracy which child will commit suicide or bring a gun to school with the intent of harming others.

### Young Adults

Young adults form the predominant clientele of university counseling centers, so information on the presenting complaints that are most prominent in this age range is largely overlapping with that for university counseling centers presented earlier. One recent study compared the prevalence of presenting issues gathered from 50 university counseling centers on two occasions across a 6-year interval. The five main presenting problems were academic concerns, relationship/adjustment issues, depression/romantic relationships, sexual issues, and eating concerns. Comparison of the earlier and more recent years revealed that the presenting complaints of students had increased in severity and chronicity. For example, longstanding, persistent depression, bipolar disorder, and schizophrenia have become more common.

Even within a somewhat homogeneous group such as university students, subgroups of students can experience quite different concerns. For example, the major presenting issues of concern to gay, lesbian, bisexual, transgender, and questioning (GLBTQ) clients are development of their social identity, isolation, educational issues, family issues, and health risks.

### Adults

The clinical presenting issues of adults are as broad as the *DSM-IV*. Depression (e.g., suicidal ideation)

and anxiety (e.g., panic attacks) are often identified by screening instruments, but other presenting issues are more difficult to diagnose. Approximately 10% of the general population experiences a personality disorder (i.e., a chronic and frequently severe condition associated with high levels of impairment and suffering in social, occupational, and other important areas of life due to an enduring, inflexible personality pattern). Roughly half of the patients seeking services from a community-based clinical setting meet the diagnostic criteria for a personality disorder.

### Mandated Clients

Clients who are ordered to receive psychological services by the courts or some other authority pose particular challenges because they did not freely choose to seek the services of the mental health professional. However, therapists cannot assume that mandated clients are unwilling clients, or that their motivation to seek therapy is different from that of nonmandated clients. Some mandated clients are willing if not eager to see the mental health professional. It is also true that many nonmandated clients seek the services of a psychologist because someone else brought them or urged them to do it. For example, children and adolescents often seek the services of a therapist at the urging or direction of their parents, and oftentimes one of the persons in a marital dyad is an unwilling participant.

Many court-ordered mandated clients are more willing to participate in therapy than might be expected. While the presence of legal charges provides some information, this information cannot be taken at face value. For example, the juvenile who took the family car and is referred to therapy because of the stated offense of auto theft is different from the youth who stole a car from the streets. Nevertheless, many mandated clients are resistant to the notion of counseling. Given this, the main tasks of the mental health professional are to elucidate the choices the client has, explain how cooperation in the client's best interest, and treat the client with dignity. Mandated clients, like nonmandated clients, need to tell their story because the presenting problem makes little sense without context.

## CODE OF ETHICS AND STANDARDS OF PRACTICE

---

At the heart of the counseling profession is the all-important relationship between the professional counselor and the individual, couple, group, or family seeking help. Because the relationship itself is so central to the helping process, ethical concerns and obligations are especially salient and compelling. This relationship entails an important power differential between the professional and those seeking counseling assistance, thus making ethical behavior an essential responsibility of the professional. Many professional counseling organizations have ethics codes and standards of practice. These codes indicate the aspirations and values of the profession and provide professional and educational guidelines applicable to a wide range of counseling endeavors. Codes also have both legal and moral consequences that are not necessarily limited to any particular professional organization. In addition to the overarching codes for counseling in general, more specific codes exist for

many situations, including school counseling, mental health counseling, marriage and family counseling, pastoral counseling, rehabilitation counseling, and group counseling. These codes have much common ground, as well as specific guidance for the particular population in question.

### Why Ethics Codes?

Society accords professionals a distinct form of respect and power that necessitates a high level of moral responsibility to avoid exploiting those who are served. Just as basic morality is necessary for the healthy functioning of the human community, ethical conduct is necessary for safe, effective professional counseling. Certain moral principles have been identified by those working in the area of bioethics that have been adopted as principles relevant to most helping professions, including counseling. The most common of these are:

- *Beneficence*: the principle that one must do good when it is in one's power to do so
- *Nonmaleficence*: the principle that one must avoid doing all unnecessary harm
- *Justice*: the principle that one must avoid partiality and seek to enact equal benefits and treatment for all those seeking assistance
- *Autonomy*: the principle that one should honor the right of human beings to have authority over decisions affecting their health and well-being

In addition to these principles, specific ethics codes have been in place for many decades in most of the counseling-related professional organizations. While they vary in length, purpose, and specificity, these ethics codes, behavioral guidelines, and standards of practice have many related functions. Often, the preface of a code will include a description of the highest, most morally admirable traits of the profession, and may detail principles similar to those mentioned above. This section alerts both the professional and the public to the parameters of the truly moral professional. Codes also serve an educational function for the counselors and clients. Since they evolve and are revised over time, codes provide the community with the contemporary standard of practice that can be expected from counselors.

Ethics codes do not necessarily carry the weight of state or federal law. Nevertheless, a violation of the

code can result in professional sanctions or removal of membership in a professional organization. Often times, laws are enacted that reflect the essence of a particular ethical mandate. Thus, ethical codes can be influential in the formation and enforcement of criminal and civil law. Having an ethics code is a hallmark of a profession. It is a defining feature that provides ideals to aspire toward, guidance for sorting out conflicting demands, and rules to obey.

### The Essence of Counseling Ethics

The ethics codes of the American Counseling Association, the American Psychological Association, and the National Association of Social Workers are relevant to those providing professional counseling. Generally, the codes address three important domains: (1) responsibilities to clients (or the recipients of professional counseling services), (2) responsibilities to other professionals, and (3) responsibilities to society at large.

#### *Responsibilities to Clients*

The welfare of the client is the predominant ethical concern of the helping professions. Ethics codes emphasize this reality by delineating the domains considered to be essential to a healthy counseling relationship. Most importantly, clients are entitled to an informed consent process that allows them to understand the helping (or therapeutic) process, make decisions regarding their participation, and have a reasonable understanding of the expected process and outcome of counseling. Clients have a right to know the theories and techniques that guide their counselor, the price of the services they will receive, the limits of confidentiality, the training and professional memberships of their counselor, and the likelihood that the counseling they will receive will be helpful. Even when counseling is involuntary, counseling ethics codes encourage practitioners to find ways to empower clients and assist them in making small informed choices.

Because the professional counseling relationship involves an inherent power imbalance, the responsibility to the client is absolute. Clients are never to be exploited for the betterment of the counselor. Anything that might threaten the counselor's objectivity and impartiality is ethically questionable. Therefore, counselors must avoid engaging in or carefully manage other roles in their clients' lives.

### ***Responsibilities to Other Professionals***

Counselors interact with other mental health professionals, school or hospital personnel, law enforcement professionals, healthcare professionals, and administrators of public or private organizations. Counselors have an ethical duty to work for the welfare of their clients while maintaining mutually respectful relationships with colleagues and employers. When policies or other professional expectations conflict with client welfare, the counselor is ethically bound to work for a solution that satisfies all parties. This is a complex mandate, and satisfying it may on occasion require consultation or mediation. However, in the end, ethics codes guide counselors to protect their clients' welfare as their most sacred trust.

Many institutions, agencies, and insurance companies have confidentiality policies that require disclosure of certain information obtained in counseling, or that allow for consultation with other professionals. This is not necessarily unethical, but clients must be informed of these policies at the beginning so they can make an informed decision about the information they are willing to disclose to the counselor.

### ***Responsibility to Human Society***

Counseling professionals are accountable to society at a number of levels. At the individual and immediate level, counselors have a duty to protect intended victims from violence threatened by clients, but must do so in a way that minimizes potential harm to the client. Professional counselors also have a duty to represent themselves and their professions accurately, and to use societal resources wisely and efficaciously.

In the aspirational section, recent editions of ethics codes are urging counseling practitioners to attend to concerns of social justice and the root causes of human distress and disability. Many writers have called for increased multicultural sensitivity in ethical counseling practices. Becoming competent to work with clients from varied cultural backgrounds is an important goal for ethical counselors, as professionals are expected to limit their practice to those areas within which they have competence.

### **Current Controversies and Future Directions**

Ethical concerns in counseling must be responsive to community parameters, cultural trends, and societal

needs. For instance, rural settings or specialized practices might necessitate a different kind of multiple-role management than larger urban settings. The challenges presented by HIV/AIDS and end-of-life choices have stimulated specific evolutionary changes in ethical guidelines for counselors. Under certain circumstances, counselors can choose to warn unaware sexual partners of clients with HIV/AIDS. They can also choose to maintain confidentiality if a terminally ill client wishes to talk about the possibilities of enacting an assisted suicide.

As healthcare costs continue to spiral out of control, stringent and limiting policies within managed care and state-funded policies present numerous challenges to ethical counseling treatment. Often, the money allocated for treatment is not sufficient to cover the costs of effective counseling. Further, counselors cannot abandon their clients without providing at least some possible alternatives for care.

These current concerns illustrate the necessity for ethics codes to evolve in response to changes in the needs and demands of the culture in which the counselor practices and the clients reside. Ethics committees and task forces within all of the major professional counseling organizations deal on a continuing basis with the daunting task of keeping ethical guidelines coherent, reasonable, current, and relevant.

## COGNITION/INTELLIGENCE, ASSESSMENT OF

---

The assessment of intelligence has a long and colorful history, and its development mirrors the development of psychology as a field. From the early work of Francis Galton and James McKean Cattell to the seminal contributions of Charles Spearman and David Wechsler to the contemporary work of Alan and Nadeen Kaufman, Jack Naglieri, and many others, the assessment of intelligence has facilitated the growth of scientific and clinical psychology. The purpose of this entry is not to provide a comprehensive review of current and promising instruments but rather to highlight important approaches to and key issues involving the assessment of intelligence.

### Assessments

There are numerous ways to classify the diverse range of intellectual assessments, but this entry uses two basic categories to facilitate the treatment of the topic: classic assessments (those based on classic theoretical and conceptual approaches to intelligence) and

contemporary approaches (those based on more recent theoretical approaches).

### Classic Assessments

#### *Stanford-Binet Intelligence Scale*

The goal of the French psychologists Alfred Binet and Theodore Simon was to examine the mental abilities of children in comparison with their average-level achieving peers. In the first couple of decades of the 20th century, Binet and Simon defined intelligence as a fundamental faculty that is of the utmost importance for practical life. They referred to this faculty variously as judgment, good sense, practical sense, initiative, and the ability to adapt one's self to circumstances. A person who lacks judgment may be a moron or an imbecile, but a person who has good judgment cannot be either. Indeed, Binet and Simon believed that the rest of the intellectual faculties were of little importance in comparison with judgment. The Binet-Simon scale required children to complete a series of mental activities until the items consistently became too difficult for them to answer correctly. The tests were normed to allow an estimate of "mental age" for each student based on the types of items they were able to answer correctly.

Lewis Terman revised and extended the Binet-Simon scale in 1912, standardized it using a large American sample, and renamed it the Stanford-Binet Intelligence Scale. Terman defined intelligence as the ability to engage in abstract thinking. Terman was well known for his work in assessing children to predict whether they would be successful later in life. He found that children who were gifted tended to be healthier, taller, better developed physically and advanced in leadership and social adaptability compared to their average-level peers.

The Stanford-Binet Scale, which was revised for its fifth edition (SB5) by Gale Roid, can be used across the lifespan. It has been normed with 4,800 participants including 1,400 children ages 2 to 5. The Stanford-Binet assesses two Domains (verbal and nonverbal reasoning) and five Factors (fluid reasoning, visual-spatial processing, quantitative reasoning, working memory, and knowledge). Each of the Factors is assessed through different subtests in each of the Domains. For example, there are verbal and nonverbal subtests for fluid reasoning. The Stanford-Binet provides a number of objects such as blocks

and colorful toys that must be manipulated to increase the attention and enjoyment of young children. The assessment takes about 5 minutes per subtest to administer.

### **Wechsler Scales**

Working primarily in the mid- to late 20th century, David Wechsler viewed intelligence as an individual's global capacity to act purposefully, think rationally, and deal effectively with the environment. Wechsler also believed that intelligence is affected by nonintellective factors such as personality. The Wechsler Intelligence Scale for Children (WISC-IV), now in its fourth edition, has been normed with 2,200 children who were matched closely to the diversity of the 2000 United States Census. The WISC-IV can be used to assess children from the age of 6 to 16 years, 11 months. It yields a full-scale IQ score and four index scores: Verbal Comprehension, which includes similarities, vocabulary, and comprehension activities; Perceptual Reasoning, which includes matrix reasoning, block design, and picture concepts; Working Memory, which includes letter-number sequencing and digit-span; and Processing Speed, which includes symbol search and coding. The subtests have not been arranged in order of importance, but instead are compiled to gauge general mental ability.

Wechsler also designed the Wechsler Preschool and Primary Scale of Intelligence, now in its third edition (WPPSI-III). The present version has been normed with 1,700 children and can be used with children ages 2 years, 6 months to 7 years, 3 months. Children under 4 years of age are administered a shorter assessment of four subtests (e.g. receptive vocabulary, information, block design, and object assembly), which measure perceptual organization and verbal comprehension. Older children are administered seven subtests (e.g., information, vocabulary, word reasoning, block design, matrix reasoning, picture concepts, and coding) to measure perceptual organization, verbal comprehension, and processing speed abilities. In its latest revision, the WPPSI-III was revised with the goal of being more enjoyable for young children and better able to sustain their attention, and to remove any ethnic, gender, regional, or socioeconomic bias.

The Wechsler Adult Intelligence Scale, currently in its third edition (WAIS-III), is administered to those 16 years old or older. The latest edition was normed in the United States during the early 1990s with a group of

2,450 people deemed to be representative of the adult population. The WAIS-III is divided into Verbal and Performance Scales. The six standard subtests found in the Verbal Scale are Information, Digit Span, Arithmetic, Vocabulary, Similarities, and Comprehension. The five standard subtests found in the Performance Scale are Block Design, Picture Arrangement, Matrix Reasoning, Picture Completion, and Digit Symbol-Coding.

### **Woodcock-Johnson Test of Cognitive Abilities**

The Woodcock-Johnson III Test of Cognitive Abilities (WJ III) offers a different perspective of cognitive assessment. The WJ III is one of the only assessments based on the Cattell-Horn-Carroll (CHC) theory of cognitive abilities. CHC theory views intelligence in a three-stratum hierarchy. The first stratum is composed of 69 narrow cognitive abilities, including memory, fluency, and coding. The second stratum is composed of seven clusters of cognitive ability, including short-term memory, processing speed, fluid reasoning, auditory processing, visual-spatial thinking, long-term retrieval, and comprehension-knowledge. The third stratum, known as General Intellectual Ability, represents a combination of all cognitive abilities. The WJ III can also be used to assess working memory and executive functioning.

The WJ III has been normed with 8,818 people in the United States and it can be administered to anyone from 2 to over 90 years old. This assessment has been normed along with the Woodcock-Johnson III Tests of Achievement, which together form the complete battery that practitioners will often administer together. The assessment is computer scored, and its results can be reported in terms of standard scores, percentile ranks, age and grade equivalent scores, and general intellectual ability. There are 10 subtests in the Standard Battery, including Verbal Comprehension, Visual-Auditory Learning, Spatial Relations, Sound Blending, Concept Formation, Visual Matching, Numbers Reversed, Incomplete Words, Auditory Working Memory, and Visual-Auditory Learning-Delayed. There are also 10 subtests on the Extended Battery. All 20 subtests are not needed at one time, but the assessment is designed to combine selected subtests to obtain the most pertinent and suitable information. The manual offers various ways to combine subtests to discern the exact information the psychologist is seeking. This assessment usually takes between 40 minutes and 2 hours to administer.

## Contemporary Approaches

### **Kaufman Batteries**

Alan and Nadeen Kaufman created two major assessments of intelligence, both of which are innovative due to their strong theoretical foundations. The Kaufman Assessment Battery for Children, Second Edition (KABC-II) has been normed with 3,025 children, and it is administered to children ages 3 years to 18 years, 11 months. The KABC-II is based on two theories of intelligence. First, the CHC model for assessment is based on a theoretical approach to intelligence that distinguishes between fluid and crystallized abilities. In the KABC-II, the CHC model is used more often because it is designed for children who speak English as a first language and would, therefore, be less disadvantaged by tests of language abilities and word knowledge. The second model, based on the neuropsychological work of Russian scientist A. R. Luria, de-emphasizes verbal processes by not including the assessments of language ability or word knowledge. This makes the Luria model more accessible to children who do not speak English as a first language, or who have an expressive or receptive language disorder.

The KABC-II was revised to provide an assessment that is more impartial when working with diverse children from various backgrounds, which resulted in less significant score variations among ethnic groups. This assessment has been standardized, adapted, and translated in more than 15 countries, and administration time typically ranges from 30 to 60 minutes.

The Kaufman Adolescent and Adult Intelligence Test (KAIT) has been normed with 2,000 people in the United States, and it is appropriate for people over the age of 11. The norm sample considered such characteristics as gender, ethnicity, examinee or parental education, and geographic region. The KAIT contains 11 subtests that compose three scales, the Crystallized, Fluid, and Delayed Recall scales. Administration takes approximately 1 hour.

### **Cognitive Assessment System**

J. P. Das, Jack Naglieri, and John Kirby proposed a planning-attention-simultaneous-successive (PASS) model of human intelligence that is partly based on Luria's neuropsychological research. Based on PASS theory, Das and Naglieri developed the Cognitive Assessment System (CAS). The CAS assesses four

aspects of basic cognitive functioning. Planning assesses cognitive control, setting goals, knowledge, and the effectiveness of one's planning strategies. Attention assesses the ability to focus on certain stimuli while ignoring others. Simultaneous processing assesses the ability to perceive stimuli as a whole. Successive processing assesses the ability to remember certain phrases and use them to better understand concepts.

The Cognitive Assessment System was standardized in 1990 on 2,200 children from diverse backgrounds. The composition of the norm group mirrors the general population in terms of gender, race, age, region, community setting, ability level, classroom placement, and parental education. The CAS can be used with children aged 5 years to 17 years, 11 months.

### **Differential Ability Scales (DAS)**

Collin Elliot has avoided the term *intelligence* and did not use it in the Differential Ability Scales (DAS-II), because of his belief that there are multiple definitions and considerable misunderstanding surrounding the term. The DAS was designed to assess cognitive strengths, weaknesses, and other abilities of children. It has been normed with 3,475 children and adolescents living in the United States, who were stratified on sex, ethnicity, age, parental educational level, region, and preschool enrollment. It is appropriate for children ages 2 years, 6 months to 17 years. The DAS was designed to reduce examinee frustration and testing time because of specific beginning and end points used for different age levels.

Two different batteries are available for administration to children: the Preschool Level is suitable for ages 2 years, 6 months to 5 years, 11 months, and the School-Age Level is intended for ages 6 years to 17 years, 11 months. The 17 subtests are divided into 12 core and 5 diagnostic subtests. The core subtests are used to compute the General Conceptual Ability composite, which assesses an individual's ability to perform complex mental tasks. The subtests are also used to compute the Verbal Ability, Nonverbal Ability, Nonverbal Reasoning Ability, and Spatial Ability scores.

### **Nonverbal Tests**

The creation and use of nonverbal tests, such as the Raven's Matrices, has played a role in intelligence testing for decades. Nevertheless, increased concern

about the confounding of language with intelligence testing has led to the development of additional nonverbal approaches to intelligence testing. Nonverbal assessments now exist for use with gifted and talented students and those who do not speak English as a first language or who have special needs.

Researchers have offered several cautions about the use of nonverbal tests. First, nonverbal assessments should be used after other assessments have first been administered. Second, although the goal is for nonverbal assessments to be helpful in assessing non-English speakers, it is difficult to find an assessment that does not have some sort of cultural bias in it. Third, the assessment procedures are nonverbal, but the cognitive processes a person uses to answer the questions may involve drawing on vocabulary words or mathematical skills. Fourth, if a nonverbal assessment is administered orally, it can no longer be considered nonverbal, because verbal skills are required to comprehend the directions. As a result, many psychologists prefer to use nonverbal assessments that involve directions that are pantomimed. For all of the reasons listed above, some psychologists prefer the use of standard, verbal assessments, such as the CAS or KABC-II, that hold promise for reducing demographic differences, but this topic remains controversial.

### **Raven's Progressive Matrices**

The Raven's Progressive Matrices (1998) is a form of nonverbal assessment that was originally designed in 1938 to assess an individual's ability to view abstract figural stimuli, reason using analogies, and draw conclusions. The Coloured Progressive Matrices is designed for children ages 5 to 11 years. The most widely used version, the Standard Progressive Matrices, is designed for those age 6 to 17 years old, but it can be used with adults also. The Advanced Progressive Matrices is designed for older adolescents and adults who have a higher intellectual ability. All three versions were constructed based on Spearman's unitary theory of intelligence.

### **Comprehensive Test of Nonverbal Intelligence**

The Comprehensive Test of Nonverbal Intelligence (CTONI) is a commonly used nonverbal assessment that consists of six subtests designed for those ages 6 to 89 years old. It has been standardized using a group of 2,901 people from 30 different states. Included in this

sample were people of diverse gender, ethnicity, age, and geographic region. The sample also included some students with disabilities who were enrolled in general education courses. The instrument measures abstract thinking abilities, problem solving, and reasoning, using a series of visual problems that need to be solved using analogical thinking, sequencing, or categorization. It requires 40 to 60 minutes to administer and can be administered orally or using pantomime.

### **Naglieri Nonverbal Ability Test**

The Naglieri Nonverbal Ability Test (NNAT) is designed for administration to children in kindergarten through Grade 12 and it has been normed on more than 100,000 students. The NNAT is useful for any students who may benefit from a nonverbal assessment, including students who are gifted and talented, learning disabled, or hearing impaired. The assessment is administered by showing diagrams of progressive matrices, so no verbal instructions are needed. This helps to ensure that the assessment is completely nonverbal to decrease the chance of any confounding variables. The NNAT takes about 30 minutes to administer and it can be administered in a group setting.

### **Universal Nonverbal Intelligence Test**

The Universal Nonverbal Intelligence Test (UNIT) is suitable for administration to children ages 5 to 17. It was standardized with a sample of 2,100 children from across the United States, and on an additional 1,765 children who were used to test its validity and reliability. The UNIT is administered by using eight language-free gestures (i.e., thumbs up, hand waving, stop, head nodding, head shaking, open-hand shrugging, palm rolling, and pointing). The UNIT consists of six subtests that assess Analogic Reasoning, Spatial Memory, Cube Design, Object Memory, Symbolic Memory, and Mazes. The UNIT, similar to other nonverbal assessments, includes matrices, but it also includes items that require the manipulation of objects and the use of gesturing, and pencil and paper.

## **Key Issues in Intellectual Assessment**

### ***Flynn Effect***

In the early 1980s, the sociologist James Flynn noted that intelligence test scores show a gradual rise in average performance over the previous several

decades. This phenomenon, which has become known as the *Flynn effect*, has been observed in almost every country and on almost every assessment (although the effect appears to be pronounced on nonverbal assessments). The increase is small (roughly 1–2 IQ points a generation) but appreciable over extended periods of time. Causes of the Flynn effect are widely debated and are beyond the scope of this entry, but the effect's primary implication for psychologists is the need to ensure that scores on intelligence tests are calculated and compared to updated norms. Flynn has documented several cases in which scores have been compared to outdated norms, leading to conclusions of superior IQ or large IQ gains when current norms would have led to more moderate conclusions.

### Giftedness

A cutoff score on an intelligence or, occasionally, an achievement test has traditionally been used to identify intellectual giftedness. For example, a school district might define a gifted student as one who scores in the top 3% to 5% on a specific intelligence assessment (e.g., the WISC-IV, SB5, or WJ III). However, in many countries a broadened definition of giftedness has emerged over the past quarter century. This change has been stimulated, in part, by recognition that giftedness can be multifaceted, that traditional intellectual assessments are limited in their ability to identify intellectual talent, and by the underrepresentation of minorities in gifted programs (i.e., the belief that current tests are biased against minority students). This has led to the development of nontraditional assessments of giftedness, including teacher and parent ratings, performance-based assessments, and peer nominations. Increasingly, the nonverbal assessments described above are also used in gifted identification systems. The impact of these alternatives appears to be limited, but a great deal of research and evaluation on the development and use of alternative assessments is needed.

### Creativity

The past decade has seen an explosive growth in research on creativity because of a growing awareness of the relationship of creativity to psychological well-being and problem-solving ability. Most conceptualizations of creativity include both cognitive and noncognitive factors, so cognitive assessment provides information on an important but limited aspect of

creativity. Divergent thinking (DT) is the most commonly assessed cognitive aspect of creativity. Historically, the Torrance Tests of Creative Thinking (TTCT) have been the most widely used divergent thinking tests. The TTCT has two versions, Verbal and Figural, and two forms (A and B) of each version. Scores can be calculated for Fluency (number of responses), Originality (statistical infrequency of the responses), Flexibility (extent to which responses appear to be from different categories), and Elaboration (extent to which responses go beyond the typical answer). The Consensual Assessment Technique, in which students produce products that can be evaluated for creativity, is a popular alternative to divergent thinking tests, but it has been the subject of limited study in applied settings.

### Major Developments

The assessments reviewed in this entry represent the main themes in cognitive assessment over the past 50 to 60 years, but there are hundreds of additional cognitive assessments available to counseling psychologists. The major developments over the past century have been the reliance on stronger theoretical models and research in the development of tests, the acknowledgment of the role of language (as both an advantage and disadvantage to certain test takers), and the realization of the need to restandardize tests on a routine basis to account for the Flynn effect.

## COGNITIVE-BEHAVIORAL THERAPY AND TECHNIQUES

---

Cognitive-behavioral therapy derives from the research protocols of hundreds of active scholars focused on a wide array of specific clinical problems. They cumulatively conclude that dysfunctional human behavior is caused or at least accompanied by irrational thinking and behavioral skill deficits; thus treatments focused on producing more reasonable thought patterns and personal-social coping skills provide the most efficient solution.

To be sure, the etiology of all human disturbances may someday be traced to biological defects, but currently such views are long on theory and short on data. Moreover, even when a pharmacological intervention may be warranted, the incremental benefits of cognitive-behavioral therapy are generally conceded.

At the core of cognitive-behavioral therapy lies the concept that people's interpretations of experiences are *beliefs* rather than *facts*, and as such, they may be accurate, rational, or irrational to varying degrees. The focus of cognitive-behavioral treatment rests on identifying and directly altering cognitions and behaviors that maintain a pattern of distress, rather than on probing into early developmental factors that may have set the stage for these cognitions and behaviors. Thus, cognitive-behavioral therapies clearly differ from the traditional psychodynamic and insight-driven psychotherapies that preceded them.

More specifically, cognitive behavior therapists posit: (a) an internal cognitive process, or "thinking," directly influences behavior; (b) this cognitive activity may be monitored and altered; and (c) desired behavior change may be mediated through a process of cognitive change. Thus external situations do not ultimately determine individuals' emotions or behavior, but rather their *interpretations* of those situations dictate their feelings and actions. An identical event may trigger disparate views among a group of

individuals, leading to dramatically different emotions and behavior. For example, two students may receive the same low score on an exam. One student interprets this event as a sign that he or she is insufficiently bright and feels a sense of failure, perhaps even contemplates a career change. The other student attributes the low grade to an unfair level of test difficulty, and feels only resentment toward the instructor. Thus, depending on how an event is interpreted and evaluated, the same external experience may lead to a wide range of eventual emotions and behaviors.

Cognitive-behavioral therapy encompasses a wide array of techniques and strategies. Cognitive-behavioral therapists argue that individuals respond to cognitive representations of environmental events rather than to the events themselves, so their interventions focus on the intricate yet functional interrelationships among cognitions, emotions, and behaviors. Although cognitive-behavioral therapy is empirically grounded and based on a manual of effective interventions, it is not a rigid approach to psychotherapy. When optimally employed, cognitive-behavioral therapy is a pragmatic and flexible process that may be tailored to the presenting needs of each client. From its origins in behavior therapy and cognitive learning science, cognitive-behavioral therapy continues to emerge as an efficient set of tools for aiding clients as they address the specific challenges of everyday life.

### Historical and Theoretical Underpinnings

The origins of cognitive-behavioral therapy can be traced to movements in the 1950s and 1960s within the existing fields of cognitive psychology and behavioral science. Growing dissatisfaction with traditional psychoanalysis and a heightened interest in learning theory led to a notable rise in behaviorally oriented therapies during the 1950s. Fortified by an arsenal of empirical findings, behavior therapy became an established mode of treatment that included techniques based on classical, operant, and observational learning.

However, by the late 1960s, discontent with strict tenets of behaviorism began to appear, even among those with behavioral proclivities. Initial attempts to include "thinking" behaviors aped the existing paradigms for modifying observable behaviors: Coverant (a contraction of *covert operant*) control, covert sensitization, and covert modeling, for example, all focused on increasing or decreasing specific thoughts, images,

and feelings deemed desirable or problematic. When Albert Ellis, Donald Meichenbaum, and Aaron T. Beck all began writing about the treatment of chronically and severely distressed individuals through cognitive approaches, the tide turned from behaviorism to cognitive therapies. Researchers demonstrated the effectiveness of cognitive therapy through tightly controlled outcome studies using random assignment and placebo controls. Soon cognitive explanations for learning-based phenomena began to be blended with the once-dominant paradigm of behaviorism, and cognitive-behavioral theories were born.

Researchers in the 1970s and 1980s began to develop specific cognitive-behavioral protocols that included strategies from forms of both cognitive and behavioral treatments. During this period, cognitive-behavioral therapy (CBT) began to be used more frequently as a manner of structured treatment for a variety of client concerns. Examples of typical CBT protocols included manualized approaches to panic control, depression, anxiety, and specific phobias. Researchers and clinicians alike began reporting that cognitive factors could be viewed as a form of behavior and, therefore, could be manipulated using previously established conventional behavior therapies. For example, behavioral techniques such as modeling, reinforcement, and problem solving were reconceptualized as tools for implementing various cognitive strategies; they were also used to explore the viability of inferences. Additionally, the cognitive-behavioral therapies involved learning experiences that were designed to change cognitions in order for behavior to become more appropriate, and, eventually, facilitate social or emotional functioning. Mounting evidence continues to support the effectiveness of cognitive-behavioral therapy for certain psychological problems.

### **Basic Features of Cognitive-Behavioral Therapy**

Although a variety of different models and interventions have been developed under the rubric of cognitive-behavioral therapy, all share certain features that are common to CBT.

#### ***Empirical Grounding***

Cognitive-behavioral therapy grew out of a precedent set by radical behaviorism that established the strong empirical verification of all clinical

procedures. Consequently, an empirical, hypothesis-testing approach is a trademark of modern cognitive-behavioral therapy. Literally hundreds of controlled clinical trials have been performed using CBT to address a wide range of problems, with the continued evaluation of specific, standardized cognitive-behavioral protocols a salient goal in the field.

#### ***Problem Focused and Goal Oriented***

In simplest form, the cognitive-behavioral case conceptualization of client concerns envisions people seeking treatment for problems they want to solve and goals they hope to attain. The cognitive-behavioral therapist works with a client to identify these problems, prioritize which ones to address in therapy, and together develop a concrete means of measuring regular progress. The process of treatment is designed to alleviate the identified problem and to assist clients in accomplishing the goals they seek. For example, a primary treatment goal for an individual suffering from panic disorder might be eliminating the symptoms of panic; secondary goals may address modifying the client's dysfunctional beliefs and thoughts so that episodes of panic will not emerge if multiple stressors accumulate in the future.

#### ***Time Limited***

Cognitive-behavioral treatments are typically brief, ranging in duration from 6 to approximately 30 sessions. However, treatment rarely exceeds 7 or 8 months in total. Treatment approaches are often based on established CBT manuals that identify specific goals for each session while recommending various techniques to accomplish these goals. The time-limited approach of cognitive-behavioral therapy has contributed to its popularity, because third-party and managed care providers place challenging limits on billing for therapy yet require a solid justification for payment in brief psychotherapy treatment.

#### ***Collaborative***

Cognitive-behavioral therapists actively collaborate with their clients, helping them solve acute problems and identify effective strategies for coping with challenges. The therapist and client communicate in a direct, straightforward manner to develop treatment goals and strategies. Discussion of problems takes

place in a transparent style that highlights any conceptual steps underlying the tactics employed. Clients play an active role and contribute to the treatment process throughout the course of cognitive-behavioral therapy.

### ***Action Oriented***

Cognitive-behavioral therapies require clients to behave in new ways in order to alter maladaptive patterns of interpreting and interacting with their environments. Novel interventions and activities are developed and performed by the client both in session and beyond in an attempt to address and eventually modify dysfunctional distortions, behaviors, and beliefs.

### ***Structured Homework Assignments***

Consistent with the active, teaching role of the therapist, homework is an important component of cognitive-behavioral treatments. Homework may include such activities as practicing specific techniques (e.g., relaxation or breathing), conducting personal experiments, rehearsing behavioral skills, or completing cognitive journals and assessments. Homework is viewed as a structured mechanism for both learning and rehearsing new skills and behaviors that require consistent practice for mastery. Homework is a cornerstone of the action-oriented approach epitomized by many cognitive-behavioral interventions.

### ***Directive Role of Therapist***

Under CBT protocols, the therapist provides active, direct assistance to clients who must confront problems they feel unable to address on their own. Irrational thoughts and cognitions are confronted by an active cognitive-behavioral therapist, who often argues the logic of these beliefs through various exercises aimed at fostering change. A therapist may also employ active modeling, role-playing, and other corrective interpretation strategies when working with a particular client. Although the process of cognitive-behavioral therapy is ultimately collaborative in nature, the therapist plays an active and directive role in many exchanges that take place in session.

### ***Emphasis on the Present***

Unlike its psychotherapeutic predecessors, cognitive-behavioral therapy is primarily focused on a client's

present-day concerns rather than mining through what has since passed. Although an understanding of the pathogenesis of problems may be helpful when considering optimal solutions to present-day concerns, the cognitive-behavioral therapist does not dwell on early etiological assertions of how problems may have developed in childhood. The CBT protocol most often addresses the cognitions and subsequent behaviors that are contributing to the client's present dysfunction, rather than the pursuit of developmental insight.

## **Overview of Cognitive-Behavioral Therapies**

### ***Rational-Emotive Therapy***

Ellis developed rational-emotive therapy in the 1950s in reaction to various aspects of traditional psychoanalysis. He proposed that irrational beliefs regarding the self and the world were cause for much suffering, including the expressions of psychopathology. Ellis identified cognitive processing errors that he described as irrational thoughts (e.g., "awfulizing," believing "I must be perfect," and jumping to conclusions). Rational-emotive therapy focuses on behavioral change, yet emphasizes cognitive persuasion and actively disputing irrational beliefs. An important contribution follows from the ABC model, wherein emotional consequences are thought to be caused by beliefs about unsettling events, not by the events themselves. These emotional consequences (C) are targeted for change by disputing the beliefs (B) about the situation (A). Ellis later moved away from a strictly cognitive approach, and his rational-emotive therapy evolved into rational emotive behavior therapy (REBT). Nonetheless, the central intervention of Ellis's work remains the identification and disputation of irrational thoughts that are deemed responsible for an identified emotional upset. Therapy involves actively persuading the client to adopt more rational cognitions through modeling of appropriate thoughts, monitoring the content of existing thoughts, and developing an awareness of the frequency of irrational thoughts and their subsequent impact on emotions and behavior.

### ***Cognitive Therapy***

Aaron Beck has played a central role in the development of cognitive-behavioral therapy. Second only to Sigmund Freud in the number of citations to his work

in the psychiatric literature, Beck published a cognitive theory of depression in the 1960s that has since grown to address anxiety, phobias, personality disorders, substance abuse, suicide, bipolar disorder, and other specific psychological problems. Beck identified a collection of faulty mental processing mechanisms to which humans are susceptible. These cognitive distortions include all-or-nothing thinking, overgeneralization, negative prediction, arbitrary inference, and selective negative focusing. In working with clinical patients, Beck noted that depressed individuals experienced a set of negative thoughts about themselves, about the world around them, and regarding the future. He labeled this negative pattern the *cognitive triad*. Beck described these damaging thoughts as both omnipresent and automatic; so much so that the patient is unaware of his or her biased cognitive processing. Beck sought to elicit a client's automatic thoughts through focused questioning and actively challenging dysfunctional attitudes. Beck also described schematic representations and beliefs that further create individuals' characteristic interpretation of everyday events. In sum, Beck asserted that depression and other psychopathology is caused by automatic and negative thoughts, such as devaluing the self or viewing the future in a reliably pessimistic way.

### **Social Learning Theory**

Albert Bandura was originally a behaviorist, but is most known for asserting the view that humans learn to fulfill their needs through active observation and evaluation of events, including social behavior. He alleged that individuals develop cognitive expectancies about what will happen in their environment, as well as beliefs about their own abilities to effectively perform tasks. Bandura's social learning theory purports that external conditions, in conjunction with individuals' thoughts about the situations, determine individuals' behaviors and emotions. Bandura developed the principle of reciprocal determinism, which suggests that individuals not only are shaped by their environment but also act upon and impact the environment with an influence that is far from unidirectional. Additionally, social learning theory states that perceived reinforcers may be more reinforcing than actual reinforcers. Likewise, in social learning theory, direct reinforcement for performing a behavior is unnecessary for the behavior to occur, as observation of a modeled performance that incurs a positively

evaluated reward is sufficient to create the behavior. Thus, in Bandura's social learning theory, cognitive processes are responsible for mediating the relationship between behavioral reinforcers and personal response.

### **Stress Inoculation Training**

Stress inoculation training (SIT) was popularized by Meichenbaum as a psychotherapeutic analogy to vaccination against a disease. SIT utilizes many of the specific cognitive-behavioral therapies previously described. It prepares clients for dealing with demanding future events by providing instruction in applying coping skills at gradually increasing levels of stress. Augmenting clients' repertoire of coping responses to milder stressors is intended to build their skills and confidence when handling more severe levels of stress. The three phases of SIT involve education about the clinical problem, coping skills training, and exposure to simulated stressors. Clients are initially exposed to low levels of stressful situations through imagery techniques, and gradually practice coping skills with the stressful events encountered in daily life.

### **Problem-Solving Therapy and Decision-Making Counseling**

Problem-solving therapy rests upon the assumption that symptoms of psychopathology are inversely related to effective problem solving, and that training in problem-solving techniques may ameliorate many maladaptive behaviors. Thomas D'Zurilla and Marvin Goldfried outlined a model of efficient problem solving that relies upon teaching clients to specify and define the problems in their lives, to generate possible solutions, and to implement those solutions judged best. Clients are trained to self-monitor their cognitive processes and to evaluate their choices and behaviors. One key component of problem solving involves the process of decision making. Decision-making counseling targets a number of tools for the collaborative generating of alternatives, gauging their relative utility, estimating probabilities of likely effects, and so forth. The literatures of problem solving and decision making overlap considerably, and some authors use the terms interchangeably. They may perhaps be distinguished in that problem solving focuses on discovering the single solution, whereas decision making weighs the trade-offs of competing alternatives.

Overall, the literature of problem-solving therapy asserts that at least one source of individual distress is a deficiency in ordinary problem-solving skills. Fundamentally, some form of problem solving is involved in any approach to psychotherapy.

## Strategies and Techniques

### ***Psychoeducation***

Individuals who receive cognitive-behavioral counseling are typically provided with educational information to facilitate the process of working on their presenting problems. Psychoeducation involves teaching individuals the key tenets of cognitive-behavioral therapy, from defining and identifying negative thoughts to understanding the impact these cognitions have on emotions and behavior. Although psychoeducation takes place throughout the process of counseling, it is used most extensively during early sessions and may be supplemented with bibliotherapy (reading materials), videos, and other educational resources. For example, in treating an individual suffering from an eating disorder, psychoeducation would likely entail exposure not only to the CBT model, but also to supplemental information addressing proper nutrition, healthy diet, and the possible medical complications associated with restricting, bingeing, or purging. In addressing issues of panic or anxiety dysregulation, the therapist must explain to the client the normal, biological elements involved in the stress process. The content of cognitive-behavioral psychoeducation may take many forms depending on the client's presenting concerns, but understanding the process of change is integral to the success of CBT.

### ***Cognitive Restructuring***

At its core, the methodology of cognitive-behavioral therapy involves identifying and changing maladaptive cognitive processes as they relate to problematic emotions and behavior. Cognitive restructuring entails teaching clients to become aware of their automatic negative thoughts, to evaluate the extent to which these thoughts are accurate or rational, and to replace irrational thoughts with more reasonable interpretations, evaluations, and assumptions. Clients are encouraged to systematically seek out and test the evidence upon which they base their predictions and views. Initially, the therapist may actively question the client's beliefs

in an attempt to uncover automatic thought processes. Various forms of self-monitoring are also utilized to aid clients in identifying, disputing, and acting against their own negative thoughts that lead to problems with depression, anxiety, anger, and other distressing psychological symptoms. Several strategies for challenging irrational thinking include examining previous experiences, exploring objective data, shifting perspectives and role playing, combating catastrophic or biased thinking, and becoming educated about relevant facts. The therapist may provide examples of more adaptive cognitive patterns while reinforcing the client's constructive efforts to develop new sets of rational schema. Cognitive restructuring is a collection of techniques that attempt to loosen and modify a client's biased perceptions in favor of more functional and constructive ways of viewing the self, the world, and the future.

### ***Social and Communication Skills Training***

Depending on the areas of identified deficit, cognitive-behavioral therapy may involve teaching clients specific strategies for increasing the efficiency of their social and relational behaviors. Modeling, practice, and performance of new skills, videotaping, and group exposure may be used to facilitate social skills training. For example, eye contact may be practiced and targeted for improvement, along with other assertiveness skills. Interpersonal conflicts may be role-played, and methods of approaching confrontation or boundary setting may be brainstormed and discussed collaboratively. Training in social and communication skills is generally considered an indispensable part of cognitive-behavioral therapy for treating social anxiety and marital distress. These strategies have also been employed when addressing depression, discontent, and conflict in a variety of interpersonal systems.

### ***Behavior Rehearsal***

Introduced by Arnold A. Lazarus in 1966, the term *behavior rehearsal* identified a specific procedure that sought to replace deficient or ineffective social and interpersonal responses with more adaptive behavioral patterns. The cognitive-behavioral therapist might play the role of some person(s) with whom the client is inhibited, under the assumption that through role-playing progress is made toward dealing with actual people and events. The therapist may also train the client to become knowledgeable about other

stressful situations or fear-provoking objects, to plan coping skills and alternate behaviors, and to rehearse these new modes of expression. Lazarus equated being rehearsed with being prepared, both of which were associated with successful spontaneous effects and the genesis of change.

### **Imagery Rehearsal**

Imagery rehearsal therapy is conceptualized as a therapeutic process that employs the human imagery system in an effort to change and rehearse new outcomes. The use of mental reproductions in an attempt to generate change is a current topic in cognitive-behavioral therapy. Imagery treatments are used in CBT to mentally rehearse behavioral alternatives that contribute to burgeoning coping skills. For instance, positive imagery may be practiced to aid with relaxation or anxiety-reduction techniques. The rehearsal of imagery also shows preliminary promise for the treatment of trauma symptoms and chronic nightmares in a variety of populations. Aspects of imagery rehearsal therapy include practicing imagery skills, selecting images for change, and manipulating or rearranging the visualization in an attempt to change the frightening thoughts into a preferred context. These new images are then rehearsed in a structured effort to enhance control of bothersome mental scenes.

### **Relaxation**

Relaxation strategies are commonly used with disorders having a basis of arousal or anxiety, but training in relaxation also serves as an adjunct to facilitate other forms of cognitive-behavioral therapy. In the 1930s, Edmund Jacobson developed a method of deep relaxation that depended upon a series of muscular tension and release exercises. This technique, known as progressive muscle relaxation (PMR), involves moving through the major muscle groups of the body in a sequence of directed tension and relaxation. The client is instructed to notice the difference between tautness and release, and to develop awareness of the sensations of relaxation. Other common forms of relaxation training include breathing retraining, meditation, and guided imagery. Various approaches to relaxation may be combined in a simultaneous or sequential approach. The overarching goal of relaxation training is for the individual to enhance his or

her awareness of unnecessary tension in the body, and to develop an ability to release it.

### **Flooding**

The process of flooding involves prolonged exposure to stimuli that evoke strong levels of anxiety or fear. This technique differs from other forms of exposure-based anxiety reduction in that flooding begins with intense exposure to highly feared situations, where other procedures allow for gradual contact. Flooding entails systematic, prolonged, and repeated exposure to fear-evoking stimuli until the anxiety and fear associated with the situation have been reduced. Flooding may take place in vivo, where exposure is to an actual, tangible stimulus, or a mental representation may be used in a second technique called *imaginal flooding*. The latter intervention is employed when it is neither feasible nor practical to conduct in vivo flooding (e.g., a therapist may have great difficulties accessing the feared situation). Flooding has typically been conceptualized as a procedure for eliminating fear, anxiety, phobias, and panic. High levels of discomfort are invariably induced in the client, yet many therapists view extended exposure to feared yet harmless stimuli as important and even essential conditions for extinction of the fear response.

### **Systematic Desensitization**

Systematic desensitization is another exposure therapy that emphasizes less intense and more gradual contact with distressing stimuli. Developed by Joseph Wolpe, systematic desensitization aims to maintain clients in a nonanxious state during the process of graduated exposure. Wolpe adopted and streamlined the technique used in progressive muscle relaxation as a method of counterconditioning, what he termed *neurotic anxiety response habits*. The client collaborates with the therapist to develop a hierarchy of anxiety-producing situations. Then, the client is induced into a deeply relaxed state and presented with a series of gradually escalating anxiety-provoking images from the hierarchy. This hierarchy might include items such as hearing that someone vomited, watching a movie where a character vomits, seeing someone vomit in real life, feeling nauseated and needing to vomit oneself, and so on. These graded visualizations are then paired with relaxation procedures, and discomfort is addressed with self-calming. When certain thresholds

of anxiety are experienced during the intervention, images are terminated and relaxed states reproduced. With continued systematic exposure, the client's levels of fear and anxiety are said to progressively weaken until the client no longer experiences anxiety in response to the once aversive circumstances.

## COGNITIVE THERAPY

---

Cognitive therapy is based on the idea that beliefs determine feelings and behavior. Albert Ellis, who along with Aaron Beck pioneered the cognitive approach to therapy, favored this quote by the Stoic philosopher Epictetus (first century A.D.): “What disturbs people's minds is not events but their judgments on events.” Cognitive therapists use a variety of techniques and approaches to identify and then modify the cognitive distortions and irrational beliefs that clients bring to counseling. Thoughts are typically defined as distorted or irrational when they do not square with reality or cannot be supported with objective evidence, and when they cause emotional problems such as depression and anxiety.

Cognitive therapists utilize the counseling relationship to educate their clients about how thinking affects feelings and behaviors. Cognitive therapists formally or informally assess clients' patterns of thinking and how their beliefs have contributed to their current problems. A variety of techniques can then be employed to help clients challenge and modify problematic cognitions. For example, the counselor and client often discuss the veracity of the client's beliefs and whether they can be defended rationally. Clients also may be asked to keep records of irrational thoughts, read books or articles about the principles of cognitive therapy, and participate in role-plays with the therapist that challenge beliefs about inadequacies clients perceive in their relationships with other people. The underlying goal of these interventions is to modify the irrational or distorted thoughts that are causing problems for the client.

Over the past several decades, cognitive therapy has been increasingly integrated with behavior counseling into a broad category labeled cognitive-behavioral therapy (CBT). Both cognitive and behavioral counseling were developed during the mid-20th century, in part because of the dissatisfaction by some with Sigmund Freud's psychoanalysis and because of emerging research on human cognition and behavior.

Classic behavioral approaches initially rejected any attempt to incorporate the role of clients' thoughts into counseling, but eventually were strongly influenced by the science of cognitive psychology. In a similar way, cognitive therapists such as Ellis and Beck initially focused very little attention on their clients' behaviors and increasingly incorporated more and more behavioral elements into their approaches.

Ellis pioneered cognitive therapy with his original formulation of what he called *rational-emotive therapy* because of what he saw as the limitations and myths associated with psychoanalysis. He has gradually reshaped it to be an integration of both cognitive and behavioral counseling, and fittingly relabeled it *rational emotive behavior therapy* (REBT). Beck initially developed his brand of cognitive therapy to explain the psychological processes that led to depression. While Aaron Beck acknowledged Ellis's influence in the development of cognitive therapy, today Beck's approach remains unique in its primary emphasis on cognitive factors in therapy. Many theorists have influenced the development of cognitive therapy in addition to Ellis and Beck, so it has much less historical cohesion than theories dominated by a single theoretician. The remainder of this entry will focus on the counseling models of Ellis and Beck, cognitive therapy's two most prominent theorists, and will conclude with a brief review of research and current trends in cognitive therapy.

### Albert Ellis's Rational Emotive Behavior Therapy

Ellis turned to philosophy, especially the philosophy of happiness, early in his own life because of anxieties in social situations. In some of his later writings, Ellis identified himself as having moved from a logical positivist point of view (a modern, scientific approach emphasizing what exists and is knowable) to a constructivist and postmodern philosophy (in which there is no absolute truth). Meaning is created, at least partly, by the individual observer. Despite our often strongly-held convictions, Ellis believes that we do not know reality, nor what reality will be, with absolute certainty.

Two general principles are prominent in REBT. First is the notion that thoughts play a major role in determining how an individual feels and behaves, and are the primary cause of emotional and psychological disturbances. Ellis worked with a client's current thought patterns and spent little time exploring the history of

how these thoughts developed. Central to REBT is the idea that specific types of irrational beliefs are particularly likely to lead to human misery. Some examples of irrational beliefs are those pertaining to

- *Competence and success*: the irrational belief that in whatever we strive to do, we must be completely successful all the time
- *Love and approval*: the irrational belief that our love must be returned by others completely and without reservation
- *Being treated unfairly*: the irrational belief that if we believe we are treating someone fairly, they must reciprocate by treating us with absolute fairness at all times
- *Safety and comfort*: the irrational belief that because we seek to live a safe and comfortable life, we cannot tolerate the inconveniences and setbacks that life presents

A second important principle of REBT concerns the active role played by the therapist. REBT counselors educate the people they work with about the basic principles of REBT, and they do not hesitate to confront irrational and dysfunctional beliefs displayed by the client. REBT is synonymous with the ABC method Ellis used to work with clients. The A refers to an activating event that caused a client to feel a certain way, the B refers to the beliefs that the client has about the event, and the C refers to the consequences that those beliefs have in terms of emotional and behavioral responses.

After ABCs are identified at the outset of counseling, the main curative effort in REBT is for the counselor to help the client dispute and change the irrational beliefs so that new effects will be realized. According to Ellis, when irrational beliefs are successfully disputed, effective new philosophies emerge and lead to healthy emotions and effective functional behaviors.

### Aaron Beck's Cognitive Therapy

Aaron Beck was originally trained as a psychoanalyst, but was influenced by both George Kelly and Albert Ellis in formulating cognitive therapy (hereafter referred to as CT). Kelly was a psychologist who developed personal construction theory, which posited that the world is perceived according to whatever meaning a person attaches to it, and that each person is free to choose different meanings in understanding the world.

Beck's early theorizing was primarily based on an information-processing model that emphasized understanding systematic distortions of external events and internal stimuli that ultimately result in depression. He categorized and discussed these distortions in his writings, and in many ways they are similar to the types of irrational beliefs Ellis identified in REBT. Examples from cognitive therapy include *arbitrary inference*, coming to a conclusion, when there is no evidence, or even contrary evidence, for the conclusion; *selective abstraction*, paying attention to a selective piece of information, without looking at the other information or considering the situation as a whole; and *overgeneralization*, drawing a conclusion from very limited information.

Beck noted that underlying these distorted interpretations of events are relatively enduring cognitive structures called *schemas*. Schemas are core beliefs, developed throughout life, that affect people's interpretation of events at a fundamental level. A person's schemas dictate the types of information he or she pays attention to, and lead to the cognitive distortions and automatic thoughts about the situations a person encounters in life. Based on these ideas, Beck described the presence of a negative cognitive triad that he believed is present in depression-prone individuals: negative views about the world, negative ideas about the future, and negative thoughts about the self. Beck labeled this the *cognitive specificity hypothesis*, and expanded it to postulate a distinct cognitive profile for each psychiatric disorder. For example, the cognitive profile of depressed individuals may include self-devaluation, which is evident in the negative cognitive triad, while the cognitive profile for anxious individuals may include fears about their vulnerability to future threats.

As with REBT, raising the clients' awareness of the influence that thoughts have on negative feelings is viewed as essential. One notable difference between CT and REBT is Beck's emphasis on what he termed the *collaborative empiricism* between the counselor and client. Whereas an REBT counselor may take a more directive, educational stance with a client, Beck favored a more collaborative process. The counselor and client work together using whatever evidence they have to determine if a given belief is distorted.

Thought stopping, positive imagery, and positive self-talk are also often used in cognitive therapy. *Thought stopping*, which can be as simple as saying "stop" to oneself, is used as a way to break the negative thought cycle. *Positive imagery*, asking the client

to imagine a positive outcome, can help challenge negative automatic thoughts. *Positive self-talk*, which involves saying positive, affirming things to oneself, is also a way to interrupt the negative thought cycle. Beck also suggested giving clients homework by having them attempt to modify thoughts in everyday life situations between sessions.

## Research Support

There is considerable research evidence documenting the effectiveness of CT, which explains in part the strong continued interest in developing and refining both cognitive and cognitive-behavioral therapy. For example, support for the efficacy of REBT was found in reviews of 70 and 28 outcome studies. The efficacy of CT was the subject of a review of 14 meta-analyses, a statistical method of summarizing the results of numerous studies on the same topic. Another research review of an aggregate of 325 studies involving more than 9,000 subjects indicated that CT was effective with a number of different psychological problems including adult and adolescent depression, anxiety disorder, social phobia, and marital distress. The research support for CT and REBT is one of the reasons it is often labeled an *evidence-based treatment* for disorders such as anxiety and depression.

## Future Directions

A number of theorists have taken core features of cognitive therapy and expanded both its theoretical underpinnings and its applicability to different types of clinical issues. Jeffrey Young and colleagues developed *schema therapy*, an application of CT for clients with personality disorders. They noted that personality disorders represent rigid and inflexible traits that are enduring. The general goal of schema therapy is to help clients with personality disorders repair maladaptive schemas developed early in life and to change maladaptive coping styles.

Donald Meichenbaum's *stress inoculation training* (SIT) represents an important integration of cognitive and behavioral therapies. This approach attempts to "inoculate" a person from stress in a manner analogous to the way the body reacts to a virus or bacteria by forming antibodies after a vaccination. Meichenbaum uses a three-stage approach. During the conceptual phase the counselor establishes a collaborative relationship with clients, gathers information about their

concerns, and provides education about the role of thinking and emotion in maintaining stress. In the skills acquisition phase clients are taught coping skills that can be used in stressful situations. For example, a client may be taught relaxation strategies and the use of positive self-statements. In the application and follow-through stage, clients implement what they have learned in life, and they work with the counselor to evaluate their effectiveness.

Zindel Segal, J. Mark G. Williams, and John D. Teasdale developed mindfulness-based cognitive therapy (MBCT) by integrating cognitive therapy with Jon Kabat-Zinn's mindfulness-based stress reduction (MBSR) in order to prevent relapses of depressive episodes. Mindfulness in contemporary psychology has been conceptualized as nonjudgmental, present-centered awareness. Mindfulness entails acknowledging each thought, feeling, or sensation that arises nonjudgmentally and with acceptance. Kabat-Zinn's MBSR consists of a program of eight weekly 2-hour sessions and includes such elements as meditation and yoga. In MBCT, Segal suggested that mindfulness practices be used to help individuals shift their relationship to the thoughts, feelings, and bodily sensations that contribute to depression. Rather than attempt to change the content of thoughts, as suggested in Beck's CT, participants in MBCT are trained to view their thoughts as transient mental events that are not necessarily fundamental parts of themselves or accurate depictions of reality.

Cognitive approaches to therapy are widely used and researched. The vitality of this approach is evidenced in an extensive body of research, and in continued developments in its applicability to a wide of clinical concerns. Ellis and Beck have training institutes that offer extensive training in REBT and cognitive therapy, respectively. These institutes continue to produce trained therapists and teachers, to play an important role in establishing credentialing standards, and to provide direction for continued research on these approaches.

## COMMON FACTORS MODEL

---

The study of psychotherapy has yielded important insights into the predictors of clinical improvement. One major focus of the psychotherapy outcome literature has been to determine the most efficacious treatment models or techniques. For example, is cognitive therapy (CT), in which therapists focus on helping clients identify and challenge irrational thoughts, more effective in treating depression than interpersonal psychotherapy (IPT), in which therapists encourage clients to discuss and troubleshoot problems in their social relationships?

Reviews indicate that the number of psychotherapies has increased approximately 600% since 1960 and the number of psychotherapeutic treatments models is greater than 200. Are each of these therapies fundamentally different, offering clients help in separate ways, or might they share more in common than one might expect? While proponents of the various models claim that techniques and strategies specific to their models account for client change, research indicates

that the *mechanisms* responsible for change may not differ according to theoretical approach. The *common factors* theory stems from the contention that much of the effect of the various psychotherapies is due to factors that psychotherapies share, rather than those that are unique to a particular type of therapy. Researchers estimate that common factors account for between 45% and 70% of the effects of psychotherapy. This is in comparison to an upper bound of 8% accounted for by specific techniques.

### The Dodo Bird

Seventy years ago, Saul Rosenzweig introduced the concept of common factors in what has become a classic article, noting that apparently diverse forms of psychotherapy appear to be similarly successful. Attempting to capture the peculiarity of this phenomenon, Rosenzweig invoked Lewis Carroll's *Alice in Wonderland*, noting the dodo bird's proclamation that "Everyone has won, and all must have prizes." The finding that most psychotherapies tend to have similar rates of efficacy has subsequently been labeled *the dodo bird conjecture*.

Ironically, the empirical basis of common factors research was spurred by Hans J. Eysenck's controversial outcome study, in which he found minimal, custodial treatment to be more effective than psychotherapy. In response to Eysenck's work, researchers set about rigorously demonstrating the beneficial effects of psychotherapy. Mary L. Smith and Gene V. Glass used meta-analysis, a statistical method that allows for the findings of many research studies to be combined, to establish the therapeutic effect of psychotherapy. They combined the results of more than 375 studies and provided compelling evidence in support of the efficacy of psychotherapy. Subsequent meta-analyses have confirmed the efficacy of psychotherapy over no treatment. Most striking, however, is that meta-analytic findings are consistent with Rosenzweig's original proposition that different psychotherapies have approximately similar effects. In the most extensive meta-analysis of psychotherapy treatment studies to date, Bruce E. Wampold and colleagues found no evidence of differential treatment effects.

This finding leads to a paradox. Treatments with different theorized mechanisms of change yield quite similar results. Thus, psychotherapies could be like radiation and chemotherapy, completely different, yet similarly effective treatments for the same illness.

Alternatively, they could be quite similar in their active ingredients, like two aspirin-containing pain relievers marketed under different brand names. Common factors researchers investigate hypotheses related to the latter.

### The Common Factors

The lack of a consensual operational definition of the term *common factors* has posed a problem for researchers, and there are three widely cited organizational schemes for categorizing the factors. Rosenzweig's original model included four common factors: (1) catharsis, (2) the personality of the good therapist, (3) the therapeutic ideology, and (4) the alternative formulation of psychological events. Julia D. Frank and Jerome B. Frank also listed four components as necessary: (1) a healer in whom faith is placed, (2) a conceptual scheme or myth consistent with the assumptive world of the client and therapist that makes sense of the symptoms, (3) a locality that is imbued with the power of healing (e.g., hospital, psychologist's office), and (4) a task or procedure that demands effort and is a vehicle for maintaining the therapeutic relationship. The final organizational approach identifies five broad categories of common factors: (1) client characteristics, (2) therapist qualities, (3) the therapeutic relationship, (4) change processes, and (5) treatment structures. Although these categories are not mutually exclusive (e.g., therapist qualities are likely not independent of the quality of therapeutic relationship, and the therapeutic relationship may be considered a change process by some), this approach is useful for the purposes of succinctly describing the extant literature on common factors.

### Therapist Factors

Although recent outcome research has primarily focused on determining the most effective treatments for specific groups of clients, reanalyses of these studies indicate that the therapist may be a more important factor in determining outcome than the type of treatment. On the average, the therapist accounts for approximately 6% to 9% of the variability in outcomes. This is in contrast to the variability among treatments, which is approximately 1% at most. This finding is consistent with the common factors hypothesis, since if the most important determinants of change are shared across therapies, then the qualities of the

person implementing the therapy should be of more importance than variations in type of treatment.

Although the therapist appears important in determining psychotherapeutic change, empirically clarifying the qualities of an effective therapist has been a challenging task. This question remains important in regard to the common factors hypothesis. Although therapist variability may indicate that certain pantheoretical therapist characteristics are critical to helping clients, the finding that the therapist accounts for differences in client outcome may be related to differential skill in implementing or fidelity to a particular therapy's techniques.

Findings consistent with the latter explanation noted above would be inconsistent with the common factors hypothesis and lend support to specific theoretical explanations of psychotherapy. However, *treatment adherence*, or the degree to which a therapist faithfully performs the techniques of a particular therapy (and does not perform the techniques of other therapies), has not consistently predicted clinical outcome. Furthermore, analyses indicate that therapist demographic variables (type of training, years of training, theoretical orientation) do not differentially contribute to client outcome. It is important to note how this differs from what one might expect in more traditional medical settings. For example, one would expect that a surgeon who more closely follows the accepted protocol for an appendectomy would be more successful than one who does not.

Instead, the most commonly cited beneficial therapist trait is the rather generic *positive descriptors*. More specifically, a recent meta-analysis demonstrated that client ratings of therapist empathy were significant predictors of therapy outcome, accounting for approximately 7% to 10% of variance in outcomes. Reanalyses from a large clinical trial indicate that more effective therapists: (a) tended to focus on the psychological versus biological aspects of depression, (b) were more likely to be psychologists than psychiatrists, (c) used psychotherapy only rather than in combination with medication, and (d) expected treatment to take longer. Thomas M. Skovholt and Len L. Jennings analyzed the interviews of 10 psychotherapists who were nominated by colleagues as *master therapists* and reported that such therapists described a number of common traits. Among these were descriptors such as (a) a desire for lifelong learning, (b) valuing cognitive complexity and ambiguity, (c) attention to their own emotional well-being and

how it may influence their work, and (d) relational competence that is utilized in therapy. Although it remains unclear how these descriptors influence therapeutic change, it seems clear that therapist qualities that cut across convenient theoretical boundaries are among the most important predictors of psychotherapeutic change.

### ***Client Factors***

Although among the least cited factors, the characteristics of the client may be among the most important ingredients in effective therapy. Positive expectation and hope are the most frequently cited of these client factors. E. Fuller Torrey noted that faith in the institution (e.g., seeking treatment or merely walking in the door) may lead clients to improve.

Specifically, expectation can be operationalized as cognitions regarding the likelihood that an event will occur. A significant body of research has addressed the construct of client expectations, and findings confirm that expectancies are significant predictors of psychotherapy outcome. If clients believe they are likely to improve by engaging in therapy, they often do. Expectations about counseling have an important impact on decisions to begin or remain in psychotherapy and on the effectiveness of psychotherapy in general. Those with positive expectations are more likely to begin psychotherapy, invest more fully in the therapeutic process, remain in therapy even when it is difficult, and experience positive outcomes.

### ***Relationship Factors***

The relationship between therapist and client is the most widely cited and researched common factor, revealing robust findings and generating a significant body of literature. The genesis of the therapeutic alliance can be traced back to Sigmund Freud's early papers in which he noted the importance of positive attachment between the analyst and the patient. In 1975, Edward S. Bordin formally presented the first pantheoretical notion of alliance in his presidential address to the Society of Psychotherapy Research. He argued that the alliance was composed of three related components: (1) bonds, (2) tasks, and (3) goals. Specifically, *bonds* referred to the interpersonal attachment in psychotherapy; *tasks* were the agreement surrounding what is to be done in therapy; and *goals* were the degree of consensus between therapist

and client relative to long- and short-term outcome expectations. Recent meta-analyses indicate that measures of the therapeutic relationship derived from this construct are moderate predictors of treatment outcome. There is also evidence supporting the *tear and repair hypothesis*, which holds that therapeutic relationships that involve a period of decline (i.e., tear) that is followed by periods of improvement (repair) may actually be more indicative of successful therapy than therapeutic dyads with static or even steadily increasing relationship quality.

Researchers such as Carl R. Rogers held that the empathic bond between a client and therapist was sufficiently powerful to induce change in and of itself. In Rogers's view, the role of the therapist is to facilitate a collaborative and genuine interpersonal relationship with the client and unlock the client's own natural tendency toward growth and development. Psychodynamic theories (the most direct descendents of Freud's psychoanalysis) include direct discussion of the relationship between client and therapist as the central ingredient central in successful therapy. More specifically, psychodynamic therapists contend that clients tend to repeat the maladaptive patterns of past relationships in the therapy session and that is the role of the therapist to make these patterns explicit so that they can be discussed openly and be changed.

Others, such as Aaron T. Beck, the founder of cognitive therapy, argued that an adequate therapeutic alliance is important in that it allows for the client and therapist to engage in the primary work of cognitive approaches, namely, examining the validity of irrational automatic thoughts and determining problematic cognitive schemas. Integrative therapists such as James P. McCullough, the developer of the *cognitive-behavioral analysis system of psychotherapy* (CBASP), have argued for a more robust discussion of the therapeutic relationship in cognitively oriented therapies.

Research provides no clear answers in regard to the respective validity of the above claims. Thus, it remains possible that the therapeutic relationship has an impact on clinical outcome in different ways across therapies (as suggested by the various theories above). However, it is important to note that, as yet, findings do not support significant differences in the effect of the therapeutic alliance in regard to therapy type (e.g., interpersonal, cognitive behavior, active, and placebo pharmacotherapy with clinical management). Consistent with the common factors hypothesis, this finding indicates that despite divergent theories regarding

the therapeutic relationship, the mechanisms mediating its effects on clinical outcome may be quite similar.

## Change Processes

Change processes are the means through which therapeutic change is thought to occur. Approximately 30 commonalities have been identified under this subheading, the most frequent of these being: (a) opportunity for catharsis, (b) acquisition and practice of new behaviors, (c) provision of rationale, (d) fostering insight/awareness, and (e) emotional or interpersonal learning.

Numerous findings illustrate the importance of providing a therapeutic rationale that is acceptable to clients. The rationale addresses both the cause of the presenting concern and the approach chosen to address that concern. Participants prefer counseling theories that are congruent with their personal epistemology, and congruence of client worldview and psychotherapeutic theory is positively related to outcome.

## Treatment Structures

Treatment structure is the specific implementation of the rituals and techniques particular to a certain treatment. All effective treatments have rituals and related techniques. The most frequently cited factors related to treatment structure are: (a) use of techniques/ritual, (b) a focus on the "inner world"/exploration of emotional issues, (c) adherence to theory, (d) interacting participants, (e) communication (verbal/nonverbal), and (f) explanation of therapy and participant roles. Research on treatment structures suggests that it does not matter which specific treatment approach is followed as long as the chosen approach includes the above factors. Thus, although evidence supporting the importance of *specific* structures or techniques is lacking, the presence of structure and techniques *in general* appears to be an important common factor.

## COMPUTER-ASSISTED TESTING

---

Computer-assisted testing is the use of computers to support assessment and testing processes. This entry focuses on the history, varieties, and future directions of computer-assisted testing.

### History

Computer-assisted testing began in the early 1950s when optical scanners were adapted to read special answer sheets and score tests. This resulted in the widespread use of multiple-choice tests in a variety of testing applications. As mainframe computers became more available, the use of computers in testing expanded.

The first expansion focused on extracting more information from scores on tests with multiple scores. Thus, in addition to scoring tests, computers began to interpret test scores and analyze test data. Score profiles on a number of tests were interpreted by experts,

and their knowledge was embodied into computer-generated interpretive reports for instruments scored on multiple scales. Notable examples include the Minnesota Multiphasic Personality Inventory and the Strong Interest Inventory. Interpretive reports have been expanded and improved over the years and are in prominent use today for a number of educational and psychological instruments.

The second expansion occurred in the late 1960s. As computers became more accessible in education, mainframe computers were equipped with multiple terminals that could display information on cathode-ray terminals and accept responses by keyboard. These “dumb” terminals were connected to mainframe computers by dial-up modems that functioned at speeds of 10 to 30 characters per second. Rudimentary “time-sharing” software polled the terminals for responses and transmitted information to the terminals. These hardware configurations gave rise to the first generation of computer-assisted instruction (CAI).

CAI in the 1960s and 1970s consisted of computers functioning as “page turners,” with very basic branching logic to support the instructional process. A screen was presented to the student, the student made a response, and rudimentary computer software determined the next screen to present to the student. Computer-based testing, using the same page-turning approach, was a natural result of this process.

Initially, time-shared computers administered tests on a question-by-question basis. However, communication between terminals and mainframe computers was very slow. The response times of the time-shared systems were unpredictable, and sometimes delays of a minute or more occurred between test questions. This problem seriously affected the standardization of the testing process and the acceptability of CAI. As a consequence, neither CAI nor computer-based testing was very successful in those years.

The development of the minicomputer in the early 1970s was the major hardware advance that allowed computer-assisted testing to flourish. Minicomputers were small (relative to mainframes, but large by today’s standards) and provided a single user with complete access to the hardware and software. As a consequence, software dedicated to the testing process could be written and run independently of other applications. This allowed almost complete control over the system response time between test questions and faster

throughput time, resulting in better standardization of the testing process. These capabilities were further enhanced as the personal computer (PC) became widely available in the mid-1980s. Today's PCs using multithreading and high-speed microchips allow computers to perform extensive computations in fractions of a second.

## Varieties of Computer-Assisted Testing

### **Conventional Testing**

The simplest application of computers in test delivery is the administration of conventional tests in which all examinees receive the same test questions in the same order, usually a question at a time. Although this seems like a trivial advance over paper-and-pencil tests, it has a number of advantages. First, all instructions are presented by computer, prior to the examinee receiving the test questions, typically along with some practice questions. This insures that each examinee has read and understood the instructions. Second, scores can be made available to the examinee or test administrator immediately after completion of the test. Furthermore, all examinee responses are recorded electronically, thus eliminating the need to optically scan test answer sheets. The amount of time it takes the examinee to respond to each question can be recorded. This information can be useful in evaluating the examinee's attention to the task, and it provides information about the examinee's processing time that might be useful for evaluating his or her performance. No paper is used in the testing process, thereby reducing the expense of reproducing the test materials and filing paper records. Finally, the testing process can be enhanced with audio, video, and color, thus making it possible to measure traits not easily measured in paper-and-pencil test administration.

### **Branched or Response-Contingent Testing**

Branched or response-contingent testing is useful in measuring variables that can be evaluated through a problem-solving scenario or sequence of steps. In this approach, a problem situation is presented to the examinee with a number of alternatives. Each alternative "branches" to a different second stage in the problem-solving process. Subsequent branches for each subsequent question continue to lead to different changes in the situation presented to the examinee. As

a consequence, each examinee can follow a different pathway through the problem-solving process, some of which lead to an appropriate solution to the problem whereas others do not.

These "situational" tests are typically scored in terms of the adequacy and efficiency with which an examinee arrives (or does not arrive) at a solution to the presenting problem. Perhaps the most successful implementation of computer-assisted branched tests is in medical training. In this application, hypothetical patients are presented to medical students, along with information that they can access about the "patient." The student attempts to "cure" the patient by ordering various medical tests and evaluations, drawing conclusions from the information made available interactively through the test, and requesting additional information as needed. The exercises vary in level of difficulty and in the information supplied to challenge the student's knowledge and skills.

### **Partially Adaptive Testing**

Adaptive tests are designed to adapt to each examinee as the testing process is implemented. Branched or response-contingent tests are adaptive in that sense, but partially and fully adaptive tests take this process further.

Partially adaptive tests operate from a bank of questions that is structured by difficulty. The simplest of these tests consists of subsets of questions grouped into short tests, or *testlets*, comprising questions of differing average difficulty levels. A testlet of medium difficulty is administered, one question at a time, and immediately scored. Examinees who score high on the testlet then receive a more difficult testlet. Those who score low are then administered an easier testlet. If only two testlets are given to an individual, the test is a *two-stage* test. A *multistage* test involves the administration of three or more testlets, with the difficulty of each subsequent testlet based on the examinee's score on the previous testlet.

In the testlet approach, *branching* is based on the examinee's score on each testlet. One variation of this approach involves branching after each question is administered. This allows examinees to move more quickly toward questions that are consistent with their ability level. Other possible partially adaptive structures have also been developed, but they are seldom used because they do not make good use of a question bank. The exception is branched testlets that are used

for measuring skills such as reading comprehension, where a number of questions are asked about a given reading passage.

### ***Fully Adaptive Testing***

Fully adaptive testing, based on a family of mathematical models called item response theory (IRT), is currently the most used approach to adaptive testing. A fully adaptive computerized adaptive test (CAT) has the five following requirements and characteristics:

1. It uses a question bank in which all questions have been calibrated by an appropriate IRT model. The IRT family includes models for questions that are scored in two categories (e.g., multiple choice scored as correct or incorrect, true or false, yes or no) and rating scale questions that are scored as multiple categories.
2. Preexisting information about each examinee (e.g., his or her school grade) can be used as a starting point for selecting questions.
3. Questions are administered one at a time, and the examinee's score is estimated after each question is answered.
4. After each question is administered, the entire question bank is searched and the question that will provide the most precise measurement of that examinee (given the examinee's score at that point in the test) is selected for administration.
5. This process of selecting and administering a question and rescoring is repeated until a suitable termination criterion is reached. Fully adaptive CATs can be terminated when the examinee's score reaches a prespecified level of precision, when there are no more useful questions in the bank for measuring a given examinee, or when the examinee has been reliably classified with respect to one or more cutting scores.

Fully adaptive CATs based on IRT are dramatically shorter than conventional tests, and they reduce the time required for test administration by 50% to 90%. They can measure individuals at much higher levels of precision than conventional tests of the same length. Furthermore, for tests with questions scored in one of two categories (e.g., correct or incorrect), most examinees will answer about 50% of the questions correctly regardless of how high or low their score is. Low-ability examinees are likely to experience the test as

“easier” than similar tests that they have taken, because the CAT will have adapted to their ability level by giving them easier questions. Conversely, high-ability examinees will experience the test as more difficult than many they have taken. As a consequence, the “psychological environment” of the test is better equated for all examinees, resulting in an appropriately challenging testing environment. Fully adaptive CAT has been implemented in a number of major testing programs.

### ***Sequential Testing***

Many have referred to sequential tests as CATs, but they are a separable set of procedures. Sequential tests are typically used to make a classification decision (e.g., to hire or not to hire, to graduate or not to graduate, or whether someone is or is not depressed) using one or more prespecified cutoff scores. Typically, the questions in the test are ranked in order of how much precision they contribute to making the classification decision. Then, the questions are administered in ranked order until a classification can be made. In contrast to fully adaptive CAT, questions are not selected based on the examinee's trait level—indeed, sequential tests generally are not designed to measure continuous traits. Since test termination is individualized in sequential testing, however, sequential tests might differ in length among a group of examinees.

### ***Current Issues and Future Directions***

Since the advent of the Internet in the late 1990s, a considerable number of tests are delivered through the Internet. Although 20 years of research demonstrated that rigorously designed computer-administered tests were equivalent to or superior to paper-and-pencil tests, the developers of most Internet or Web-based tests have given little thought to equivalence (i.e., Internet or Web-based tests have not been rigorously designed). Consequently, substantial differences might exist between tests delivered on a PC and those delivered through the Web. These differences can affect the standardization and validity of some tests. Some of these factors include:

- Different browsers use different settings for fonts, colors, and other display characteristics to deliver Web-based tests. These potentially render a given question differently to different examinees. In addition, differences in screen size and resolution reduce the

equivalence of Web-delivered tests to PC-delivered tests. On a PC, the test administration software standardizes the display for all examinees, and a standard monitor can be used throughout a testing room.

- Web access and response time vary greatly from question to question. Some of the factors that affect response time include the speed of the examinee's connection and the amount of traffic on the Web at the instant the examinee responds and receives a new question. Response time is further affected by the speed of the Web server and the other demands on the Web server. For CATs, the computational server time necessary to estimate trait level and select the next question is yet another factor that affects response time. By contrast, on a PC, only a single person is being tested at a time and between-question response time is virtually instantaneous, thus better standardizing test delivery.

- When tests are administered in an uncontrolled environment, such as might occur with Web delivery, environmental variables present during test delivery can affect the test performance of individuals. A basic principle of well-standardized testing is that paper-and-pencil tests are to be administered in a quiet and comfortable environment. For the most part PC-based tests also have been administered in testing rooms with a carefully controlled environment. When tests are delivered through the Web, however, a wide variety of extraneous factors might be present that interfere with—and potentially invalidate—the resulting scores. In addition, when individuals take tests without supervision, it is impossible to know who is actually taking the test, what materials they were accessing during test administration, and who was assisting them during testing.

Clearly, considerable research needs to be done to evaluate the comparability of Web-delivered tests to PC-delivered and paper-and-pencil tests. Before Web-delivered tests can be assumed to be replacements for other testing modes, the effects of their lack of standardization and of the physical conditions of testing on test scores must be evaluated. Furthermore, Web-delivered tests must be delivered under supervised conditions to ensure test integrity and validity.

Although computer-assisted testing has made possible the development of new kinds of tests that can take advantage of the multimedia capabilities of PCs,

that promise has yet to be realized. Very few computer-administered tests focus on the measurement of new abilities, skills, and personal characteristics that cannot be measured by paper-and-pencil tests. Unrealized possibilities include the development of tests to measure personality characteristics in new ways (e.g., using interactive scenarios and video) and new approaches to measuring individual differences in traits such as memory, reasoning, and complex perceptual skills. These developments, combined with fully adaptive CAT, will help computer-assisted testing to realize its full potential.

## CONFIDENTIALITY AND LEGAL PRIVILEGE

---

### Confidentiality

Confidentiality is the legal and ethical duty of therapists not to reveal information about their clients to unauthorized individuals. Legally and ethically, therapists are bound by statute and by the profession's code of professional conduct not to reveal information about their clients to unauthorized individuals. Legally and ethically, clients have the right to prevent their therapist from disclosing information shared by them in counseling without their consent.

In counseling, two types of confidentiality are commonly recognized: content confidentiality and contact confidentiality. *Content confidentiality* requires that the substance or content of the client's discussion with a counselor not be revealed by the professional. Disclosures of confidential client information to individuals with no right to that information are called *content breaches*. Such breaches of confidentiality may result in civil liability to the therapist or licensure revocation. *Contact confidentiality* requires that the professional not reveal the fact that the client is being seen by the professional. Disclosures to an unauthorized party that the client is seeing the therapist are referred to as *contact breaches*. Although therapists often make strenuous efforts to avoid disclosures of the identities of their clients, the law generally does not address matters of contact confidentiality.

The ethics codes of both the American Psychological Association (APA) and the American Counseling Association (ACA) provide a set of standards and code of conduct to guide the professional activities of their members, including the provision of counseling and psychological services. In both codes, the duty of counselors and therapists to protect and uphold their clients' right to privacy is fundamental, and both generally are interpreted as including the protection of contact confidentiality. Nevertheless, it is important that counselors and their clients understand the distinction between content and contact confidentiality, as most laws governing the confidentiality of counselor–client communications do not protect contact confidentiality.

Therapists' obligations to protect their clients' confidentiality derives from the client's right to privacy, which itself derives from the more general, but central, ethical value of personal autonomy—a person's right to

“self-determination.” In this case, it is the right to determine with whom personal information may be shared. Confidentiality in this sense can be understood as the counselors' duty or obligation to support clients' right to privacy by not repeating to or sharing with others information shared privately with them by their clients. What clients consider to be private must stay private, and it is the duty of therapists to assure that this is the case with respect to disclosures made by clients in counseling. If a client's private information is to be shared with another, it should be shared by the client—or at least with the consent or authorization of the client. In this regard, a client's right to privacy and a client's right to confidentiality in relation to communications shared in counseling are one and the same.

Because confidentiality and privacy are a client's right, the client may waive that right if he or she chooses. In making such a waiver, it must be demonstrated that such waiver is undertaken knowingly and voluntarily. That is, counselors may ethically and legally reveal a client's confidences with the *informed consent* of the client.

It is often suggested that the protection of another's privacy through the maintenance of confidentiality is a way to build trust within the counseling relationship—trust necessary for clients to share productively and personally with their counselors and therapists. In this regard, it is not uncommon to find it argued that an assurance of confidentiality is indispensable for effective therapy. In keeping with this view, counselors and the counseling profession generally assume that an assurance of confidentiality is essential for effective therapy and that most clients would not feel safe discussing personal and intimate aspects of their lives with a counselor without such assurance. Even the courts have embraced this assumption, with the U.S. Supreme Court writing in *Jaffee v. Redmond* (1996),

Effective psychotherapy depends upon an atmosphere of confidence and trust in which the patient is willing to make a frank and complete disclosure of facts, emotions, memories and fears . . . For this reason, the mere possibility of disclosure may impede development of the confidential relationship necessary for successful treatment.

This may be the case for some clients; however, both experience and research demonstrate that many clients are quite willing to talk personally and intimately with their counselor or therapist without

assurances of confidentiality. While some studies suggest that assurances of confidentiality are essential to productive counseling, overall the results of research on this topic are mixed, with other studies indicating that such assurances have little effect on encouraging disclosures, or that assurances of confidentiality matter only to some clients in some circumstances.

For this reason, the protection of client privacy and the maintenance of confidentiality cannot rest on their necessity to the effectiveness of therapy or as critical therapeutic tools or strategies. Rather, privacy protection and confidentiality must be justified on ethical and legal grounds. Both the APA and the ACA include the therapist's duty to protect the confidentiality of client disclosures made in counseling as a fundamental ethical principle and duty in their respective ethics codes. With regard to law, state and federal law also protect the (content) confidentiality of communications between clients and their therapists. Importantly, state and federal laws also address how such confidential communications are stored (e.g., the maintenance and management of case records) and how that information can be released—specifically, the restricted circumstances under which such information may or must be shared, and the mechanism by which that information is shared. Thus, under the law, clients' rights to privacy and therapists' obligations to protect that privacy through their maintenance of confidentiality are enforceable. However, those rights and obligations are not without limits. Exceptions to confidentiality will be discussed momentarily.

## Legal Privilege

### *Privileged Communication*

Statutes that accord protection to clients from therapists' sharing with others information that was shared privately in therapy also may include provisions exempting counselors and therapists from the requirement to reveal privileged information about a client and client disclosures in court. These laws are called privileged communication laws.

Privileged communication refers to the statutory or judicial protection extended to certain "special relationships" whose existence is considered important to the community and to be dependent on assurance of the confidentiality of communications. More specifically, in the case of therapy, it is a right, granted by statute to the client, that confidences originating in the therapeutic relationship will be safeguarded (i.e., not

be revealed) during certain court proceedings. In other words, when a client invokes privilege, the therapist is legally and ethically bound to not reveal in court information obtained during the professional relationship.

Privileged communication is understood to be rooted in early Elizabethan law, where certain individuals had the right or privilege to refuse to testify about embarrassing matters. In time, this individual privilege conferred to attorney–client relationships prohibited an attorney from testifying against his or her client. Under U.S. law, the privileged nature of communications shared by clients with their attorneys can be understood within the context of the Fifth Amendment to the Constitution—the right to avoid self-incrimination.

Over time, legislatures cautiously have passed laws extending privileged status to communications originating in other, special, socially important relationships. Such relationships include those between physicians and their patients, husbands and wives, priests and penitents or confessors. In order for legislatures to pass such laws they must be convinced that making an exception to the rule of evidence is vital to the well-being of society and that an individual citizen's need to privacy outweighs the need for evidence in a court case.

In 1961, jurist John Wigmore proposed four criteria to be used as guides to decision making regarding the according of privileged communication: (1) the communications must originate in confidence that they will not be disclosed, (2) confidentiality must be essential to the full and satisfactory maintenance of the relationship, (3) the relationship must be one that is strongly supported and fostered by the community, and (4) the harm to the relationship as a result of disclosure of the communications must be greater than the benefit from the proper disposal of the litigation.

Extension of the privilege to communications originating in therapy relationships (i.e., those occurring between psychologists or counselors and their clients) is a relatively recent development. Although it is now almost universal that *psychologist*–client communications are treated as privileged, the extension of privileged status to the communications occurring within the *counselor*–client relationship remains limited.

Even where such privileged communication is recognized, it is important for counselors to be aware that there are exceptions to this privilege that may require otherwise protected or privileged information to be revealed. Common exceptions include requirements to testify regarding client threats to the health and safety of the client or others; a client's intent to commit

a crime; knowledge of child abuse, elder abuse, or disabled adult abuse committed by the client; and a client's mental condition or state in an involuntary commitment proceeding or if the client has raised an issue of her or his mental state in a legal proceeding.

### **Qualified Privilege**

When invoked and accepted by the court, the doctrine of qualified privilege provides protection against charges of defamation. *Defamation* is an act of communication that causes someone to be shamed, ridiculed, held in contempt, lowered in the estimation of the community, or to lose employment status or earnings or otherwise suffer a damaged reputation. More specifically, defamation is the making of false statements about a person that injure his or her reputation or that deter others from associating with him or her. Libel and slander are the legal subcategories of defamation. *Libel* is defamation in print, pictures, or any other visual symbols. *Slander* is defamation by oral communication.

Of relevance to issues of confidentiality and legal privilege, defamation involves instances in which a counselor or therapist shares with another information about a client that may be or is damaging to that client's reputation. An example of this would be when therapists break confidentiality to share with the appropriate authorities (e.g., local child-protection services) their suspicion that a client is being (or has been) sexually abused or molested by an adult or, if the client is an adult, is molesting a child. Both are instances in which counselors may be required by law to break confidentiality to report their suspicions to protect a child. It is important to note that counselors are not required to be certain that abuse has taken place; rather, they are required to report their suspicions—leaving determination of facts of the matter to the appropriate authorities. Regardless of the truth or falsity of such a communication to the authorities, such a communication or revelation can be understood to be damaging to the reputation the suspected abuser, and it is understandable that such person might take legal action against the therapist for breach of confidentiality and for defamation and damage to the person's reputation and standing in the community.

In legal proceedings, the general avenues of defense in defamation suits are (1) that the communication or revelation is true, and (2) that the person gave consent to the release of the information. Qualified privilege is a third avenue of defense. The notion of there being a privilege that qualifies some communications as

exemptions from defamatory characterization rests on the notion of an overarching social duty to share or release information, even if that information may be false. There are four conditions that must be met under the doctrine of *qualified privilege*: (1) the information must be presented in good faith—not in malice, (2) there must be a legitimate social duty to release the information, (3) the disclosure must be limited in scope to what is necessary to discharge the duty, and (4) the disclosure must be made only to the appropriate parties with a right to know. Most states with mandatory abuse-reporting laws include a qualified privilege provision in their reporting statute, thereby protecting counselors from defamation suits so long as their report of suspected abuse was made out of sincere concern for the protection and welfare of the child, the information shared related only to the suspicions of abuse, and the information was shared only with the appropriate authorities.

### **Limits and Exceptions to Confidentiality and Privilege**

As noted earlier, a client's right to privacy and confidentiality, is not without limits. There are exceptions to rules of privacy and confidentiality; neither is absolute. Specific exceptions to privacy and confidentiality vary by jurisdiction, and counselors are well advised to become familiar with the exceptions that are relevant to their practice jurisdiction and professional practice setting.

In addition to previously noted client waivers of confidentiality with their informed consent, other circumstances may permit and require disclosures by counselors of otherwise confidential disclosures to supervisors and others involved in the treatment of the client. Disclosures to the parent or guardian of a minor client and disclosures to share in the interest of the operation of the system in special settings (e.g., the penal system) are additional instances when confidentiality is limited.

Even where privileged communication is recognized, counselors need to be aware of statutory exceptions to this privilege that may require them to reveal otherwise confidential and privileged information. Such exceptions may include requirements to testify regarding client threats to the health and safety of the client or others (including when a client has a fatal, communicable disease and the client's behavior is putting others at risk), a client's intent to commit a crime, reporting of suspected abuse or neglect of a child or other persons

presumed to have limited ability to care for themselves (e.g., the elderly or a disabled adult), and a client's mental condition or state in an involuntary commitment proceeding or if the client has raised an issue of her or his mental state in a legal proceeding.

Other exceptions include death of the client, sharing information with subordinate and fellow professionals in coordinating client care (e.g., within-agency or within-institution sharing of information), working under supervision, the use of clerical staff and other assistants who handle confidential information, and clinical and legal consultation with colleagues or experts. Additionally, privilege and confidentiality are waived when clients bring law suits claiming emotional damage, when clients raise issues of their mental health in legal proceedings (e.g., in custody suits), when counselors provide services to multiple clients (e.g., when a third party is present during the communication, such as in couples, family, or group counseling), and to permit counselors or therapists the ability to defend themselves against charges of negligence or malpractice charges raised by their clients.

## CONSTRUCTIVIST THEORY

---

The influence of postmodernism's challenge of the "objectivist" position in psychology has been central

in the evolution of constructivist therapies. The abandonment of the certainty of modernist positions for the tentative, constructed meanings in the postmodern world has given rise to a number of therapeutic approaches that eschew well-established, contemporary icons in psychology. Objective assessment of personality, abilities, and psychopathology has given way to a more interpretive, hermeneutic approach to understanding the world in which we live. The spirit of uncertainty that pervades postmodern discourse is evident when trying to provide a fundamental definition of constructivism.

Robert A. Neimeyer noted that there are numerous positions in postmodernism and that they are sometimes discordant with each other. He and Donald E. Polkinghorne, among others, have argued that the constructivist movement in psychotherapy is characterized by a truly postmodern lack of foundationalism, a lack of agreement on many of the particulars of how individuals construct reality. In general, constructivist theorists have an intellectual allergy to the metaphysical realist position that sets forth an understanding of the world that is independent of our own, human experiences of the world. According to the 2007 *APA Dictionary of Psychology*, *constructionism* is

the theoretical perspective, central to the work of Jean Piaget, that people actively build their perception of the world and interpret objects and events that surround them in terms of what they already know. Thus their current state of knowledge guides processing, substantially influencing how (and what) new information is acquired. (p. 221)

There are several points of view that are based on constructivist ideas; two of the best known are *radical constructivism* and *social constructionism*. Radical constructivists such as philosopher Ernst von Glasersfeld and psychotherapy pioneer Paul Watzlawick of the Mental Research Institute hold that all we can know of the world are the products of sensory/perceptual processes that take place within our bodies. The radical constructivists do not deny, in a solipsistic way, the existence of reality outside. Rather, they argue that there is no eidetic correspondence between what is "out there" and our internal perceptual constructions. Paul Watzlawick's well-known metaphor invites the reader to imagine he or she is piloting a large ocean liner through an impenetrable fog at night. In such circumstances, the ship's captain has no direct visual

representations of the rocks or icebergs that might lurk in the darkness. The captain must rely on the iconic representations given by radar and sonar and other electronic sensing devices, to make interpretations about what is “out there.” Successful adaptation, under these circumstances, is not measured by how accurately the captain was able to describe what was “out there,” but by whether or not the ship crashed into the rocks. So, for the radical constructivist, sensory/perceptual habits that endure are regarded as reality.

Another constructivist approach is that of social constructionism. It owes an intellectual heritage to Peter L. Berger and Thomas Luckman’s early work, *The Social Construction of Reality*. There are several more recent extensions of that early work by Kenneth J. Gergen, Theodore R. Sarbin, Donald E. Polkinghorne, John Shotter, and others. Sarbin and John I. Kitsuse open their collection of essays on social constructionism with the story of three baseball umpires reflecting on their professional practice of calling balls and strikes.

The first, a self-confident realist, says, “I call ’em the way they are,” to which the second who leans toward phenomenological analysis says, “I call ’em as I see ’em,” and the third closes the discussion with “They ain’t nothin’ until I call ’em.” (p. 1)

The third umpire illustrates the central premise in constructionism—that human beings are active agents in processing information and creating knowledge rather than passive organisms who simply respond to the environment. Although most constructivists acknowledge there is a “real world” outside of human consciousness, they are more interested in people’s constructions of their worlds than how close those constructions are to any objective “truth.” Social constructionism moves the interpretive act of reality construction away from people’s interior constructions to a social endeavor heavily reliant on language, customs, culture, and other contextual factors. The social constructionists move beyond the constructivism of von Glaserfeld, Watzlawick, and George Kelly by invoking the social nature of human meaning making. Social constructionism, then, adds a layer to the radical constructivist’s formulation by including the social nature of reality construction.

The social constructionist view owes its early intellectual heritage to the work of Lev Vygotsky and others. Gergen is perhaps the most well-known American psychologist writing about social constructionism. The

essential feature of social constructionism is the notion that reality construction is the result of meaning-making activities that take place in relationships with other people and in cultural/environmental/linguistic contexts. Although language is frequently seen as the primary constituent of social constructionism, language is but one aspect of the cultural/biological context that influences meaning construction. Social constructionists are interested in epistemological understandings of how we come to adapt to the varieties of realities we construct.

### Therapeutic Approaches Based on Constructivist Theory

Constructionism has found expression in a variety of psychotherapeutic approaches. Kelly is usually identified as an early example of the application of constructivist theories to therapy. He developed personal construct theory and elaborated the idea that people approach their phenomenological world much like scientists: generating theories, testing hypotheses, and revising their expectations of the world based on these experiences. Kelly did deny the existence of a reality “out there”; he thought that we all construct a different “out there” based on our experiences and expectations. Kelly called his particular philosophy *constructive alternativism* to reflect that everyone constructs an alternate reality based on his or her unique experiences. The Repertory Grid interview he developed allows clinicians to understand the unique constructs of their clients and how those constructs influenced their perceptions and behaviors.

At the same time that Kelly was developing his personal construct theory, the anthropologist Gregory Bateson was developing an approach to treatment of disorders based on radical constructivism. Bateson’s team originated the seminal idea in American psychology that the origin of psychological difficulties was in the interactions between people. The well-known double-bind theory of schizophrenia was an early attempt to explain the effect of interpersonal communication on psychological development.

The solution-focused therapies of Steven de Shazer’s group and the solution-oriented variations of William H. O’Hanlon and Michele Weiner-Davis arose in the 1980s and represented a move away from radical constructivism to a more pragmatic focus on problem resolution. The rising influence of social constructionism has enabled therapists to develop

approaches based on contextual formulations of problems and their resolutions.

The most dramatic example of this trend is seen in the work of therapists who employ a narrative metaphor in their work. Although there is a group of therapists that refer to themselves as *narrative therapists*, there is a strong narrative tradition in psychoanalysis as well. Narrative therapists, for the most part, derive their working metaphors from literary criticism and hermeneutics. The influence of narrative therapists can be seen in their influence on more conventional therapies. Recently, some cognitive-behavioral therapists have begun to describe their work as having a basis in constructionism.

### Research Support

A body of research support for constructivist therapies is growing. Practitioners of constructivist theories are generally unsympathetic to positivist approaches to research. Accordingly, the tradition of empirical studies involving carefully constructed experimental controls on treatment is sparse for constructivist therapies. Empirical support for constructivist therapies has come largely from case studies and anecdotal reports.

Solution-focused brief therapies (SFBT) have been more widely researched in recent years than any other approach. A recent review of 15 controlled studies of the effectiveness of SFBT found that SFBT provided significant benefits. Solution-focused brief therapy has been demonstrated to be effective in working with at-risk junior high school students, high school bullies, juvenile offenders, older adults, adolescent substance abusers, and university counseling center clients.

Empirical evidence for narrative approaches also exists. Narrative therapy has been reported to be successful in treating abuse, older adults, and athletes. Robert G. Malgady and Giuseppe Costantino and their colleagues have demonstrated the usefulness of narrative therapy in working with Hispanic children and adolescents.

## CONSULTATION

---

The defining moment for most products that have reached an iconic status is the generic application of the product's name, such as the use of "Kleenex" to indicate any brand of tissue. Similarly, the practice of consulting has reached a comparable level of renown and one is able to find it in almost every aspect of our present society. Today, in any given business or academic arena, one can locate listings for financial consulting, international consulting, executive sales and marketing consulting, and even nutritional consulting. Historically, the term *consulting* existed more frequently as a verb and

predates society's current trend toward life coaches who "consult" on issues such as career, relationships, and communication styles. This entry on consultation emanates from a psychological frame of reference that addresses different forms of consultation and the competent and ethical practice of consulting.

## Consulting Defined

The act or art of consulting is typically tied to solution seeking. It can be thought of as a set of helping behaviors in which one party is seeking input, advice, or feedback from another related to a problem, question, or dilemma. Several authors within the field of counseling psychology, such as Sandra Shullman and John M. Whiteley, have traced the origins of consulting to the early guidance days of Frank Parsons during which counselors and psychologists worked diligently in business settings and industrial organizations to solve vocational problems for groups, as well as individuals.

Perhaps most notable in the early life of psychological (mental health) consultation is the seminal work of Gerald Caplan with his prevention-based book titled *The Theory and Practice of Mental Health Consultation*. This work presented prevention- and developmental-based intervention options for mental health professionals that would take place outside of the therapy room. By doing so, it created the opportunity to apply psychological principles through assistance or advice in outreach types of activities. An outline of Caplan's four types of consultation would typically include client-centered case consultation, consultee-centered consultation, program-centered consultation, and administrative consultation. Since Caplan's work, consultation has been broadened to include school counseling and education, advocacy, group, and process consultation. Work in these arenas may be theoretically based on behavior-oriented, (industrial) organizational, or social justice-based solutions. Their underpinnings, though, can be connected to the early works of Caplan.

## Types of Consultation

### *Collegial Consultation*

One common form of consultation is the informal or formal exchange of information that occurs in the professional lives of counselors as they move toward refining their own clinical techniques; establishing expertise

in a particular faction of study; or improving upon a design, method, or approach. In the field of counseling, practitioners are taught to seek consultation when faced with complicated issues that are not always well defined in textbooks or evidenced-based research. A common situation that requires consultation is the realization of a potential ethical dilemma involving clients, colleagues, or students. Thus, consulting with another professional allows for the translation of what may appear abstract or unknown into observations or behaviors that others have studied and/or experienced, and for which solutions have been developed.

### *Agency Consultation*

In more formal settings, such as businesses, consultation often occurs in the context of a contractual relationship between the consultant, who holds some expertise in a specified area, and the consultee, who has identified a need or potential need but does not have the knowledge or skills required to address the issue. The consultant is held in the role of "expert" and proceeds to clarify the consultee's goals or referral questions and then sets out to analyze the situation through the study of a group, system, or process. This can incorporate direct assessment of a person or groups as well as indirect observation and data collection from others. Subsequently, the consultant interprets and outlines the results for the consultee in an effort to assist in potential problem solving or identification of structural issues, concerns, or conflicts. In most instances the consultant is collaborating with the consultee to arrive at the point of problem resolution. This mode of consultation is the essence of the scientist-practitioner model of counseling psychology. The science is manifest in the methods of investigation and research of the issues at hand, while the practice is applied through the skills of the counseling psychologist as he or she intervenes and facilitates the process.

## Stages of Consulting

The literature has demonstrated that, similar to the therapy process, the consultation experience includes different stages or phases that originate with a well-grounded working relationship. The importance of a working relationship in counseling may seem self-evident, but it is equally important in the consultation process. If rapport is not present, productivity is limited. As with therapy, the phases of assessment, conceptualization, and

solution development are often taking place as the consultant continues to build the consultation relationship. Once a working relationship has been established, clearly defining the problem, concern, or issue at hand becomes paramount to the success of the consultation process. Whether the identified need is an organizational issue of reduced productivity or a work group's difficulty in successful management of differing opinions, the participants must have a common definition of the concern as they begin their process.

Once such groundwork is clarified and understood by the engaged parties, the goal setting and problem solving may begin. It is important to remember that parallel to therapy, this understanding should be reviewed often as the consultation proceeds. Clarifying the consultation process, in addition to evaluating ongoing progress or assessing outcomes, is crucial to the successful maintenance and completion of the consulting relationship. The positive termination of a consulting relationship is dependent on a cooperative understanding of the tasks at hand and the skillful facilitation of an accountable, working relationship.

### Competency Standards

Perhaps one way to ensure competent consulting in today's mental health professions is to better quantify and define the basics of competency-based training, course work, and field experiences. As noted, there has been a proliferation of consulting "professionals" in today's job arenas. One can easily locate a number of corporate- or business-related consulting career titles available in any given phone directory or Better Business Bureau listing. Additionally, there are now persons from fields outside of psychology who promote themselves as consultants in a multitude of areas, such as retirement, spirituality, personal fitness training, athletic activities, and fashion.

The need for increased professional clarification in psychology-based consultation has been recognized through the timely efforts of the American Psychological Association's (APA) educational workgroups. The workgroups propose and outline benchmarks in an attempt to delineate boundaries of practice, developmental progress, educational requirements, internship, and practice and supervision needs. Such efforts point to a desire for more quality control in the area of consultation and a more systematic approach to the training of psychologists in the area of consultation. Likewise, Stewart E. Cooper, and numerous authors from industrial/organizational, school psychology,

military, and counseling psychology backgrounds, organized a special issue of the *Consulting Psychology Journal of Practice and Research* in 2002. This collection offered a summary of training needs and proposed working definitions of consultation as well as competency standards. These authors also called for increased research and ethics to be applied to consulting. If indeed the area of consultation is unique from the process of therapy, then it stands to reason there should be a set of skills, related literature, research, and standards that can be employed to measure a trainee's ability development. Continued APA workgroup involvement throughout each of psychology's areas will address the uniqueness of consulting and guidelines to ensure quality delivery of services.

## COPING

---

Coping refers to a complex set of behaviors and cognitions that individuals use to deal with stress and adversity. The concepts of stress and adversity are explicitly

linked to coping. Understanding coping is fundamental to understanding how stress affects people.

## The Nature of Coping

Since the 1980s the most widely accepted definition of coping has described coping as (a) constantly changing, (b) involving both cognitions and behavior, (c) effortful, (d) concerned with the management of specific demands, and (e) present when demands from within or outside of a person are evaluated as taxing or exceeding that person's resources.

Key features of this definition focus on the process of coping, noting that coping is not traitlike. Coping fluctuates across situations, although there is also stability in coping. The management aspect of this definition also is emphasized. Coping efforts may not always be successful. Some of the cognitive and behavioral strategies individuals use to manage stress lead to better adjustment, while other strategies result in worse adjustment. A third feature of the definition is that coping is a psychological construct, in that it involves evaluations or appraisals of a situation as exceeding a person's resources to manage the situation. Finally, coping involves voluntary and effortful responses. Individuals respond in broad ways to stress, and those responses include both voluntary and involuntary (automatic) reactions. Coping refers to the effortful responses people make to manage a situation or their emotional responses to it.

Coping behavior is only one part of a broader set of constructs referred to as *coping processes*. Richard Lazarus, Susan Folkman, and their colleagues describe the coping process as consisting of appraisal, behavior, and reappraisal. Appraisal involves an evaluation of the extent to which a situation is challenging, benign, or harmful, and an assessment of the internal and external resources available to deal with the situation. Coping behavior follows this appraisal, and then a reappraisal is made to determine the extent to which the coping behavior had the desired effect.

## Functions of Coping

One way of classifying coping behaviors, now regarded as overly simplistic, is as having either an emotion-focused or a problem-focused function. *Emotion-focused coping* refers to people's efforts to manage their emotional responses to stress. Examples include reframing the problem, venting, distracting oneself, and denial. *Problem-focused coping* refers to

efforts to solve the problem. These efforts can be directed inward or outward. Examples of problem-focused coping strategies include thinking about solutions, taking direct action to solve the problem, shifting one's focus, and seeking help from others. Both types of coping can be adaptive and both can be harmful, depending on the precise behavior enacted and the nature of the situation.

Recently, researchers have suggested that the functions of coping be considered in light of challenges and threats to the basic human needs for competence, relatedness, and autonomy. From a motivational perspective, all individuals have basic needs to feel competent, to relate and be connected to others, and to make independent decisions. When viewed from this perspective, the function of coping is distinguished not by the coping behavior used but by the extent to which it is a response to attacks on core needs.

## Structure of Coping

Two primary ways of thinking about types of coping are whether the coping behaviors involve active or approach (sometimes called engagement) strategies or avoidant (sometimes called disengagement) strategies, and whether the behaviors involve cognitive or behavioral strategies. *Active* coping behaviors are characterized by a willingness to interact with the stress, either internally or externally. Coping efforts that fall into this framework include cognitive reframing (thinking about the problem situation differently), acceptance, problem solving, and emotion regulation. In contrast, avoidant coping behaviors reflect an unwillingness or inability to confront the problem. *Avoidant* coping behaviors include denial, avoidance, and wishful thinking. Involuntary responses to stress (e.g., emotional or physiological arousal, intrusive thoughts, and emotional numbing) are not regarded as coping per se. Proactive coping is an additional form of coping that is not assessed by most coping inventories. *Proactive* coping consists of efforts undertaken in advance of a potentially stressful event to prevent it or to modify it before it occurs.

Recently some psychologists have suggested that a hierarchical system be developed for grouping coping strategies, but no such system has been forthcoming to date.

## Measurement of Coping

Questionnaires are the most frequently used method of assessing coping. Observational methods and

interviews are used rarely. The Ways of Coping Checklist and the COPE are the two measures of coping most often used with adults. Popular options for assessing coping in children and adolescents include the Adolescent Coping Orientation for Problem Experiences Scale (A-COPES), the Children's Coping Strategies Checklist (CCSC), the Coping Response Inventory, and the Responses to Stress Questionnaire (RSQ). Theoretically driven measures that were developed and validated using Confirmatory Factor Analysis are preferable to measures developed using other strategies. The COPE, CCSC, and RSQ are excellent examples of such measures.

Most general measures of coping have both dispositional and situation-specific versions. Dispositional measures ask about the coping strategies the individual uses with a broad array of stressors. Situation-specific measures assess coping strategies used to deal with a specific event or class of events (e.g., peer rejection or job loss). Both dispositional and situation-specific measures of coping tap some forms of active and avoidant coping. For example, problem solving, positive reframing, support seeking, distraction, and avoidance are common coping behaviors on many inventories. Additionally, some inventories assess humor, religious coping, or drug or alcohol use as a means of coping.

In addition to measures that assess a wide array of coping behaviors, there are measures designed to assess very specific types of coping in great detail. For example, a number of measures are specifically designed to assess religious coping. These measures are designed to capture subtle differences within the broad category of religious coping, and are useful for in-depth study in a particular area. Other coping inventories are designed for specific stressors such as health conditions (e.g., cancer, depression, infertility or chronic pain), and life situations (e.g., marital problems, job loss, or death of a family member).

The choice of measure used in a study of coping should depend on both the quality of the measure and the specific aims of the study. With the exception of proactive coping, which may go unstudied because it is hard to detect, many coping inventories assess the most commonly observed coping behaviors.

### **Why Coping Matters: Links to Adjustment**

A key reason for psychologists' concern about how best to categorize and measure coping is that people's

success in dealing with situations that tax their resources affects their mental and social adjustment. The goal underlying attempts to group coping strategies is to determine which coping strategies are most adaptive. Although definitive conclusions are premature, it appears that both youth and adults who use active coping strategies and versatile coping behaviors in response to stress demonstrate better psychological and physical health. In contrast, individuals who rely on avoidant coping demonstrate worse adjustment. Avoidance may be necessary in the short term to permit the individual to achieve some distance from the stress; ultimately it is harmful to psychological and physical well-being.

### **Influences on Coping**

Given the importance of coping, psychologists are engaged in an effort to understand what influences coping, particularly if changing coping as a way of improving adjustment is the goal of the counselor. Coping behaviors are influenced by a broad set of factors, including qualities of the individual, aspects of the specific situation, and pressures in the environment.

#### ***Individual Influences on Coping***

Qualities of the individual that influence coping include age, gender, socioeconomic status, temperament or personality, beliefs, and values. Girls and women are more likely than boys and men to seek social support when confronted with stress. Cognitive coping strategies increase over time; adolescents are more likely than school-age children to use cognitive coping strategies. Optimistic adults and Type A individuals (i.e., those who are hard-driving, achievement oriented, and impatient or hostile) are more likely to use active strategies and less likely to disengage from stressors than individuals who are pessimistic or not Type A.

Personality factors can serve as coping resources in times of stress. Individuals for whom religion is important are more likely to endorse spiritual forms of coping than individuals who do not hold religious values. Individuals who place a high value on maintaining relationships with others will engage in coping that repairs relationships to a much greater degree than individuals for whom this is not a salient value.

### ***Situational Influences on Coping***

Aspects of the situation that affect coping include the extent to which the stressor is acute versus chronic in nature, is familiar or novel, is controllable, involves threat as opposed to loss, involves a conflict situation, and is interpersonal in nature. For interpersonal situations, the power difference of those involved is another relevant factor. For example, individuals use religious coping much more frequently in situations that are chronic and involve loss than in situations that involve more mundane everyday stress. Situations that can be changed evoke greater use of problem-focused coping strategies than situations that cannot be changed. For example, a layoff might evoke coping focused on managing affect, whereas a conflict with a friend might stimulate coping focused on repairing the relationship. Even in situations that are not controllable, however, individuals do have a choice in how they think about and respond to the stress.

Some forms of coping are influenced by qualities of the situation to a greater degree than others. Across a variety of situations, there is much greater consistency in the use of coping strategies that involve religion, avoidance via alcohol and drug use, and seeking emotional support than there is in the use of denial, disengagement, and some aspects of active coping.

### ***Environmental Influences on Coping***

Familial, cultural, and social aspects of the environment also influence coping behavior. Family socialization plays a large role in shaping how individuals respond to stressors, particularly for youth. Coping styles and strategies develop over the course of childhood and adolescence, and are heavily influenced by parents. For example, parental reactions to differences in temperament (an individual influence) can transform natural coping tendencies.

Parents influence the development of coping strategies in three ways. First, parents coach youth to engage in particular coping behaviors via direct suggestion. For example, parents might suggest that children come talk to them when they have a problem, or parents might suggest that children engage in physical activity to take their minds off a situation. Second, parents model coping behaviors. Children observe both the behavior and the consequences of the coping choices, and when confronted with a similar situation tend to enact that coping strategy. Third, parents create an environment that encourages or

discourages specific coping activities. For example, children feel freer to talk about their feelings in families that model open communication than in families where honest discourse is discouraged. The influence of these three mechanisms in teaching youth coping strategies is apparent even when individuals become adults.

Peer, work, and neighborhood contexts also shape coping responses, largely by way of the values that are reinforced in those contexts and the resources that are available. For example, in neighborhoods with high levels of collective efficacy—that is, where neighbors support one another and share child discipline—individuals are more likely to seek tangible support to cope with specific problems. In contrast, support seeking is less likely to occur in neighborhoods lacking cohesiveness.

Culture influences how parents socialize their children's coping, but it also has independent effects via the values it espouses. For example, cultures that value the needs of the group over the needs of the individual are more likely than other cultures to support coping efforts that take group needs into account.

In addition, the environment, including culture, provides tangible (e.g., money, information or specific help) and emotional coping resources. The availability of coping resources influences individuals' perceptions of the coping options that are open to them.

### **Future Directions**

Psychologists regard an understanding of coping as critically important in their efforts to help people improve their lives. Research on coping will continue to investigate how coping should be conceptualized, the ways in which coping relates to appraisal, how the coping process unfolds, individual and environmental contributions to coping, and the contexts in which particular coping behaviors are adaptive or maladaptive. The next decade is likely to see increased attention given to ways of assessing coping that capture individuals in their daily experience, and to qualitative assessments of coping.

## COSTA, PAUL T. (1942– ), AND McCRAE, ROBERT R. (1949– )

---

Paul T. Costa, Jr., and Robert R. (Jeff) McCrae are an extraordinarily productive research team that has worked together since they first met in Boston in 1975. Their more than 250 publications on personality traits and the Five Factor model have had a profound effect on personality assessment, theory, and research.

Costa was born in 1942 in Franklin, New Hampshire. After completing undergraduate work at Clark University (1964), he went to graduate school at the University of Chicago (1966–1970), where he studied human development. He taught for 2 years at Harvard and 5 years at the University of Massachusetts, Boston (1973–1978), before moving to the National Institute of Aging in Baltimore, where he and McCrae have been ever since. He is a fellow of the Gerontological Society of America and the American Psychological Association, and a past president of the International Society for the Study of Individual Differences.

McCrae was born in 1949 in Maryville, Missouri. He studied philosophy at Michigan State University (1967–1971), but switched to psychology for his graduate work at Boston University (1971–1976). He gravitated to personality measurement and psychometrics because of his interest in mathematics and the works of

Raymond Cattell. He met Paul Costa while still in graduate school, and they worked together for 2 years in Boston before moving their research team to Baltimore. He is a fellow of the American Psychological Association, the American Psychological Society, and the Gerontological Society of America.

Costa and McCrae's research reflects their enduring interest in the scientific study of personality and of the ways in which people differ from one another. Hans Eysenck had theorized that the important dimensions underlying differences among people were neuroticism and extraversion. Costa and McCrae added Openness as a primary dimension of personality and developed the NEO (i.e., neuroticism, extraversion, openness) personality inventory for use in their research on the stability of the adult personality. They later revised the inventory to add Agreeableness and Conscientiousness and named the revised instrument the NEO-PI-R. This instrument is somewhat time consuming because it assesses multiple facets for each broad trait domain, so Costa and McCrae also developed a shorter form, the Five Factor Inventory (NEO-FFI), for quick assessment at the broad domain level.

Their work at NIA has focused primarily on a longitudinal sample of aging adults in Baltimore. They have been able to demonstrate striking consistency, long-time stability, and important consequences of the traits measured by the NEO and NEO-PI-R. This was a controversial finding in the late 1970s and early 1980s. Many in psychology (particularly social psychology) had dismissed the importance or even the existence of traits. The Five Factor model has become a consensus representation in personality assessment and theory partly because of the consistency of Costa and McCrae's findings, and the agreement of their findings with results from investigations of the lexical hypothesis (e.g., Lewis R. Goldberg).

## COUNSELING PROCESS/OUTCOME

---

Counseling process refers to events, characteristics, or conditions that occur during or as a result of the interaction between counselor and client. The therapeutic relationship that develops during counseling sessions is an example of counseling process; completing homework outside of session also constitutes an event that fits within counseling process. *Process* can refer to what the counselor does with the client as well as how change occurs within the client. In contrast, *counseling outcome* refers to the results or effects of counseling. Outcomes are those phenomena that change in the client as a direct or indirect result of counseling. Presumably, process influences outcome, although research has been unsuccessful at demonstrating consistent links between measures of process and measures of outcomes.

Measurement of counseling process and outcome has been one of the most vexing tasks in the history of counseling and psychotherapy research. One of the key problems in process and outcome measurement is that while hundreds of process and outcome measures have been created, no consensus exists about what measures or how these measures should be employed in practice or research. Researchers refer to this as the *units of measurement* issue: With any particular client, or in any particular study, *what* should be measured? Process researchers have investigated such variables as the amount of talking by counselors or clients, counselor competence, therapist adherence to a role or treatment manual, client experiencing of affect, the strength of the therapeutic bond, client defensiveness or resistance, severity of client problem(s), and language use. As researchers have noted, process clearly signifies many different things.

The remainder of this entry discusses how psychological tests are typically evaluated, describes and evaluates a representative sample of counseling

process and outcome measures, and then discusses future directions for research about process and outcome measures.

### General Measurement Principles

Process and outcome measures can be evaluated using traditional standards of reliability and validity. *Reliability* refers to the consistency of measurement and is frequently evaluated through statistical tests of internal consistency, test-retest reliability, and interrater reliability. Coefficient alpha, the statistic usually employed to assess *internal consistency*, indicates the extent to which scores on individual test items contribute consistently to the total score. *Test-retest reliability* refers to the consistency of measurement over time; if the test measures a stable psychological trait, it should yield consistent scores across repeated administrations. *Interrater reliability* refers to the ability of two or more judges to assess some psychological characteristic or event similarly. The intraclass correlation and kappa statistic are used to indicate the degree of interrater reliability.

*Validity* has been described both as (a) the extent to which a test measures the construct it is intended to measure and (b) the extent to which evidence exists that test scores can be employed for a particular purpose. The first definition focuses on whether scores on a particular test reflect a particular construct (e.g., depression) as opposed to other constructs (e.g., stress) or systematic sources of error. *Social desirability* is a frequently noticed source of error for many tests and refers to the tendency to present one's self in a favorable light. In a counseling setting, for example, a new client might underreport such negative behaviors as smoking, drinking, or unsafe sexual behaviors.

Regarding the second definition of validity, organizations such as the American Educational Research Association (AERA), the American Psychological Association (APA), and the National Council on Measurement in Education (NCME) emphasize the purpose of testing as a critical factor. Given that the primary purpose of an outcome measure is to assess change, an instrument's sensitivity to change is directly related to its construct validity.

Validity can be evaluated using numerous methods. For example, researchers often examine the correlations between a test of a particular construct and a second test of the same or a similar construct (i.e., an evaluation of convergent validity). Correlations between a test of a construct and a dissimilar construct

represent an evaluation of discriminant validity. In addition, test developers frequently create tests by administering a large pool of items to a large group of respondents and then subjecting the resulting scores to a factor analysis. In factor analysis, test developers assume that any large collection of items or tests actually measures a smaller number of more basic factors or traits; these factors consist of a group of highly intercorrelated variables. *Factor analysis* refers to a set of statistical procedures used to examine the relations among items or tests and produce an estimate of the smaller number of factors that accounts for those relations.

## Process Measures

This section reviews a representative sample of five counseling process measures. The description of each measure includes an overview of the test, brief information about reliability and validity findings, a counseling-related research result found with this measure, and at least one potential problem or issue with the measure.

### Five Process Measures

*Working Alliance Inventory (WAI)*. This 36-item scale includes parallel forms that are completed by client, counselor, and observer; a short-form of 12 items has also been recently developed. The WAI measures aspects of the working alliance that Bordin suggested would grow out of an agreement between client and therapist on counseling goals and tasks. The WAI produces scores on 3 subscales of 12 items each (tasks, goals, and the therapeutic bond) and a total score. Sample items include, "I believe (my counselor) likes me" and "(My counselor) and I are working toward mutually agreed-upon goals." More than 100 studies employing the WAI have appeared in the literature, with many confirming that WAI scores evidence high internal consistency and at least modestly predict therapy outcome. Some studies have raised questions about the constructs the WAI measures, how to explain the high correlations among the three subscales, and which source (client, counselor, observer) better predicts outcome. Research also indicates that a better working alliance is associated with a client's willingness to express negative affect, a potentially important component of a successful counseling process.

*Session Evaluation Questionnaire (SEQ)*. The SEQ was developed to measure clients' perceptions of a counseling session's impact on them in terms of post-session mood and immediate effects. Twenty-four items, rated on a 7-point semantic differential scale, produce a total score and four subscale scores (Depth, Smoothness, Positivity, and Arousal). With a semantic differential scale, the two extremes of the construct are presented with the numbers between them (e.g., Safe–1 2 3 4 5 6 7 Dangerous, or Quiet–1 2 3 4 5 6 7 Aroused). Raters choose the number that best expresses their feeling. Depth items refer to the client's in-session perception of the session's value and impact, while Smoothness items assess in-session perceptions of safety and distress. Positivity measures client's postsession confidence and happiness, and Arousal refers to postsession level of activity and excitement. Research indicates that the in-session Depth and Arousal measures correlate highly with the postsession Positivity (but not Arousal) scale. Like all process measures, questions remain about the SEQ's relation to outcome, that is, to what extent does a single counseling session affect counseling outcome?

*Expectations About Counseling-Brief Form (EAC-B)*. Clients' expectations about counseling form a potentially important explanation for why clients seek counseling and what they expect to occur. The Expectations About Counseling-Brief Form (EAC-B) has been the most widely employed measure in this area for research purposes. The EAC-B contains items answered on a 7-point Likert scale that ranges from *not true* to *definitely true*. Responses to the 66 items are employed to produce scores on 17 scales that are grouped in four general areas of Client Attitudes and Behaviors, Counselor Attitudes and Behaviors, Counselor Characteristics, and Counseling Process and Outcome. Studies of the internal consistency and test-retest reliability of the subscales found support for most of the scales. Construct validity studies have demonstrated that the scale assesses expectations about counseling as opposed to perceptions about counseling. The scale has also been found to be useful with Hispanic and rural samples. Although one of the technically most sophisticated of the process measures, little published research has appeared with the EAC-B since the early 1990s.

*Client Reactions System (CRS)*. Hill and colleagues developed the CRS, a measure that contains 21

categories of reactions (14 positive and 7 negative categories) that clients experience in response to counselor interventions. Examples of the positive categories include Feelings, where the client felt more deeply; Supported, where the client feels that the counselor liked or cared for the client; Relieved, with decreased feelings of anxiety or depression; and Responsibility, where the client blamed others less and took more responsibility for events. In negative categories, Misunderstood refers to situations where the client believes that the counselor did not listen accurately, judged the client, or made false assumptions, and Scared, where the client feels overwhelmed or afraid to admit some problem. To employ the CRS, clients watch a videotape of their session, stopping the tape after each counselor intervention and then rating their reaction. Although researchers have raised questions about the reliability and validity of similar measures, relatively few studies have been completed with the CRS.

*Counseling Self-Estimate Inventory (COSE).* Bandura's self-efficacy theory forms the theoretical basis for more recent process-oriented measures. The theory's basic idea is that expectations of personal competence strongly influence the initiation and persistence of behavior. To create the COSE, Larson and colleagues administered the Likert-format items to 213 students enrolled in master's level counseling courses and performed a factor analysis on the resulting responses. Five factors resulted from the analysis. Microskills items refer to course content related to basic counseling and communication skills training. Process items describe an integration of counselor responses when working with a client. The sum of the Difficult Client Behaviors items indicates high self-efficacy for dealing with silent or unmotivated clients. Cultural Competence items refer to behaving competently with clients of different ethnic or cultural groups. Awareness of Values items assess counselors' tendency to impose their values and biases on the client.

COSE scales have demonstrated moderate to high internal consistency and test-retest reliability, and they correlate moderately in expected directions with measures of self-concept, anxiety, problem-solving appraisal, and counseling performance. A significant problem with the Process and Microskills subscales is that the content of each scale is confounded with positive or negative item wording.

### **Additional Process Measures**

Other process scales more frequently employed in the counseling literature include the Expectations about Counseling scale, Counselor Rating Form, Counselor Effectiveness Scale, Barrett-Lennard Relationship Inventory, Counselor Effectiveness Rating Scale, Personal Attributes Inventory, Counselor Evaluation Inventory, and Structural Analysis of Social Behavior. These measures tap into just a few of the many process constructs noted above.

### **Outcome Measures**

While many process measures are employed primarily in research studies, both researchers and practicing counselors use outcome measures. Counseling researchers use outcome measures to conduct efficacy and effectiveness studies. Efficacy studies are studies typically conducted in experimental settings (such as university clinics) in which a particular therapeutic approach (e.g., cognitive-behavioral therapy) is employed with counseling and control groups that are relatively homogeneous (e.g., all clients are depressed). With efficacy studies, researchers choose measures focused on the particular targets of counseling, such as depression or anxiety. In contrast, effectiveness studies occur in field settings, such as community mental health settings, where a diverse group of clients (in terms of age, gender, and race) presents with a wide range of psychological problems.

In practice settings, managed care companies and other funding sources often require counselors to employ outcome measures to offer evidence that counseling services are effective. Community mental health agencies, hospitals, and schools employ outcome measures to demonstrate that their services provide benefits to clients and their families. Outcome measures in effectiveness studies and in most practice settings are more likely to be comprehensive measures that assess a broad range of problem domains.

A corresponding set of problems to those found with process measures occurs with counseling outcome measures. For example, outcome measures differ in terms of their

1. *Content*, such as a focus on intrapsychic (e.g., feelings of anxiety and depression), interpersonal (e.g., conflict with others), and social role (e.g., student or employee) functioning

2. *Source of information*, including the client, counselor, significant others, trained observers, expert judges, and societal agents (e.g., teachers)
3. *Methods*, including self-reports, ratings by others, behavioral observations, physiological measures, and projective methods

As with process measures, no agreement exists among researchers or counselors about which combinations of content, source, or method should be employed in any particular situation. What is known is that each of these elements can influence the results of outcome investigations. Researchers have found that the degree of apparent change in counseling can be significantly influenced by the assessment method as well as the specific measure chosen. These findings include:

1. Counselor and expert ratings produce larger estimates of change than client self-reports.
2. Global ratings (e.g., an overall assessment of client functioning) typically show larger effects than assessments of specific symptoms.
3. Measures based on specific short-term targets of therapy (e.g., reduction in alcohol consumption) produce greater effects than more general long-range targets (such as future mental health status).
4. Measures of negative affective states (e.g., depression and anxiety) show larger, more immediate effects from counseling than measures of interpersonal conflict or social role functioning.

#### Four Outcome Measures

Many well-known scales employed for outcome measurement with children, adolescents, and adults, such as the Child Behavior Checklist, Conners Rating Scales, and the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), are lengthy measures initially designed to perform diagnostic and screening purposes. Many of these measures are too long, are too expensive, and contain too many items that are insensitive to change to be realistic outcome measures in practice settings. Research participants may be willing to spend an hour or more completing a battery of measures. However, actual clients whose primary motivation is to obtain relief from a troublesome condition typically will not complete tests that are more than 1 page in length, tasks that require more than 5 minutes to complete, or activities that

appear to be unrelated to the actual provision of counseling services.

This section provides four examples of outcome measures: Two are specific to depression and anxiety, while the remaining two measures represent examples of a global outcome measure and a comprehensive outcome measure.

*Beck Depression Inventory (BDI)*. Developed on the basis of observations of depressed and nondepressed individuals, the BDI contains 21 multiple-choice items that assess 21 different aspects of depression. Completed by clients, each item contains four statements that range from *no indication of depression* to *severe*. A sample item might ask respondents to choose among statements ranging from “I do not feel sad” to “I am so sad or unhappy that I can’t stand it.” Depression symptoms and attitudes include mood, guilt feelings, suicidal wishes, irritability, sleep disturbance, and loss of appetite.

Research suggests that scores on the BDI evidence high internal consistency, correlate highly with other measures of depression, and are sensitive to change resulting from a variety of medication and counseling interventions. On the other hand, some research indicates that more than 50% of individuals classified as depressed by the BDI change categories when retested, even when the retesting period consists of only a few hours or days. The instability of some BDI items raises questions about whether changes in BDI scores reflect improvements resulting from counseling or a methodological influence.

*State-Trait Anxiety Inventory (STAI)*. The STAI consists of two 20-item self-report scales that are based on a conceptual understanding of anxiety as a signal to an individual of the presence of danger. The State Anxiety scale assesses more transient emotional states that can vary by situation, while the Trait Anxiety scale focuses on more stable aspects of anxiety. Sample items include “I feel content” and “I feel nervous.” Research evaluations of the two scales show expected differences; the State Anxiety scale, for example, evidences lower test-retest reliability. Both the State and Trait Anxiety scales evidence high internal consistency across most samples. The State Anxiety scale has been shown to be treatment sensitive, particularly in detecting the effects of counseling interventions aimed at decreasing test anxiety. Although the STAI was developed with the intent to produce scores that better reflect anxiety than

depression, most measures of anxiety and depression correlate moderately to highly. This finding has not been explained satisfactorily, and it raises questions about the validity of measures of anxiety and depression.

*Global Assessment of Functioning (GAF).* Over the past several decades, the GAF has been the most widely used brief outcome measure. Its popularity is attributable in part to the fact that it consists of a single-item 100-point rating scale that clinicians complete to estimate a client's overall functioning and symptomatology. The global rating is intended to summarize symptoms and functioning across diverse domains from work functioning to suicide potential over daily, weekly, or monthly periods. GAF ratings employed for outcome assessment are typically completed at intake and termination. However, managed care companies often require counselors to report such ratings for individual clients over more frequent time intervals while counseling is ongoing.

Researchers have reported modest test-retest reliability values in the .60 to .80 range. Despite its widespread use, little additional psychometric data are available. The most fundamental problem with the GAF is its transparency: The counselor can easily manipulate the rating, making the client appear as distressed as necessary to justify treatment, but at a potential cost of validity. A recent survey found that counselors considered global GAF-type data to be among the least useful information for outcome assessment.

*Outcome Questionnaire (OQ-45).* One of the newest comprehensive outcome scales is the Outcome Questionnaire-45 or OQ-45. Intended for persons 18 and older, the 45-item test can be completed in about 5 minutes. The OQ produces a total score and three subscale scores. The *Symptom Distress* subscale contains items related to anxiety and depression (e.g., "I feel blue"). Interpersonal Relations items assess satisfaction with and problems in interpersonal functioning (e.g., "I am satisfied with my relationships with others"). Social Role Performance items relate to satisfaction and competence in employment, family, and leisure roles (e.g., "I find my work/school satisfying").

Studies indicate that the OQ-45 has adequate test-retest reliability and internal consistency. Scores on the OQ correlate in expected directions and magnitudes with scores on related scales such as the SCL-90-R, Beck Depression Inventory, State-Trait Anxiety Inventory, and Inventory of Interpersonal Problems. Furthermore, OQ-45 scores can distinguish between clinical

and nonclinical groups. A source of concern is that research with college students found that students show improvement on OQ items even when they are not in counseling, although not at the same rate as treated individuals. An additional issue is that all three subscales of the OQ-45 are highly intercorrelated, suggesting that the total score on the scale provides an indication of general distress. Nevertheless, some of the most interesting outcome research now being conducted has demonstrated that using OQ scores to provide ongoing feedback to counselors about client progress reduces the rate of client treatment failures.

## Future Directions

Traditionally, test developers have sought items that discriminate among individuals on relatively stable traits (e.g., intelligence or vocational interests). A more challenging task is to measure change. Test developers are now at work developing a second generation of tests to measure changes that occur as a direct or indirect result of counseling. Empirical studies of methodologies that can be used to evaluate and enhance change-sensitive measures have only recently begun to appear in the professional psychological literature. A major assumption guiding these approaches is that different test construction and item analysis procedures are necessary to select items that reflect counseling effects. These item-analysis procedures test the competing claims that an observable change at the item level results from counseling, or that change results from factors that are unrelated to counseling. These efforts may enable researchers and counselors to eventually obtain better answers to such important questions as "What changes in counseling?" and "What is the nature of the process that produces beneficial change in counseling?"

## COUNSELING SKILLS TRAINING

Training in counseling skills originated in 1966 and resulted in the microcounseling training approach to teaching interviewing skills and the publication in 1968 of the first monograph separate in the *Journal of Counseling Psychology*. Since that time the microcounseling approach to teaching single skills of counseling, interviewing, and psychotherapy has become the standard and more than 450 databased studies have examined its efficacy. Meta-analyses have concluded that microcounseling is effective for teaching a wide variety of helping skills to a variety of populations.

Forty years of research and theorizing has demonstrated microcounseling's merit as an educational paradigm for counselor and therapist education. Microcounseling has since evolved into a comprehensive generic framework that describes not only the training process but the skills, dimensions, and processes of therapy and effective communication in general. Microcounseling sees the training process and therapy not necessarily as separate entities, but as part of a larger whole, the goal of which is to help people lead intentional, effective, and positive lives.

### Origins and Development of Skills

The identification of the first microskill of attending behavior is illustrative of the theory and practice orientation of the counseling skills approach. In 1966, video was new to the helping profession and few had ideas on how to use this new medium. Allen Ivey and Weston Morrill asked a volunteer “counselor trainee” to conduct a videotaped interview. Fortunately, the trainee was ineffective and the team review of the video revealed that the beginning counselor (1) failed to maintain eye contact, (2) moved her hands and legs nervously, (3) had a tense vocal tone, and (4) awkwardly changed topics and ended up talking about herself. The opposite of these four behaviors were named *attending behavior*; now a generic part of the language of the helping field. The trainee was returned to the interviewing room with feedback and then conducted a vastly improved session with another client. Furthermore, 2 days later the trainee commented joyously that she had attended to her husband and that they had enjoyed a “beautiful weekend.”

The next skill to be identified was the skill of reflection of feeling (“You feel . . . because . . .”), and other listening and influencing skills soon followed. These

first identified counseling skills became the basis of social skills training. Skills training in communication is often the basis for management training, nutrition counseling, AIDS peer counseling, medical interviewing, and many other types of counseling. From 1968 to 1970 Ivey demonstrated the effectiveness of teaching hospitalized patients basic communication skills. Patients who had been in a Veteran's Administration (VA) hospital for years were successfully trained and released to the community without further therapy.

Microcounseling instruction in each skill is followed by practice sessions with feedback and a focus on generalization of each to the "real world" of interviewing practice.

Critical to this entire process is the identification of observable, countable behavioral skills that are verifiable and that produce predictable results in client verbal and nonverbal behavior. B. F. Skinner lauded the microcounseling approach as indicative of how reinforcement patterns could affect the counseling and therapy process, while humanistically-oriented counselors decried the scientific orientation of the system.

During the next decade many contributors added skills, and by the mid-1970s a comprehensive Microskills Hierarchy of skills and dimensions was formulated. Conceptually, the Hierarchy rests on a foundation of ethics, multicultural issues, and wellness. Built on this foundation, in successive layers, are attending behavior skills, the basic listening sequence, five-stages of interviewing, and influencing skills. The Hierarchy (see Figure 1) represents the cumulative impact of years of clinical teaching experience and research.

### **Predicting Results From Intentional Use of Interviewing Skills**

Experienced counselors who use questioning skills can reliably predict the kind of response their clients will next make. However, trainees are encouraged to intentionally flex and be prepared with a new skill when the skill they are using does not produce the expected results in the client. Two example skills are presented below that exemplify intentional prediction.

#### **Open and Closed Questions**

Open questions often begin with *who*, *what*, *when*, *where*, and *why*. Closed questions may start with *do*, *is*, or *are*. Questions beginning with *could*, *can*, or *would* are open, but they are somewhat closed in that

they permit the client to more easily say that they don't want to respond.

The predicted result is that clients will give more detail and talk more in response to open questions. Closed questions elicit specific information, but they also discourage extended client responses. Effective questions encourage more focused client conversations with more pertinent detail and less wandering. A danger of questions, of course, is that the counselor may take too much direction and control in the session.

#### **Reflection of Feeling**

This involves identification by the interviewer of the key emotions of a client and a restatement of them back to the client to clarify and focus attention on the client's affective experience. With less verbal or reluctant clients and children, the brief acknowledgment of feeling may be more appropriate than detailed exploration of complex feelings, as exploration of emotions may be uncomfortable.

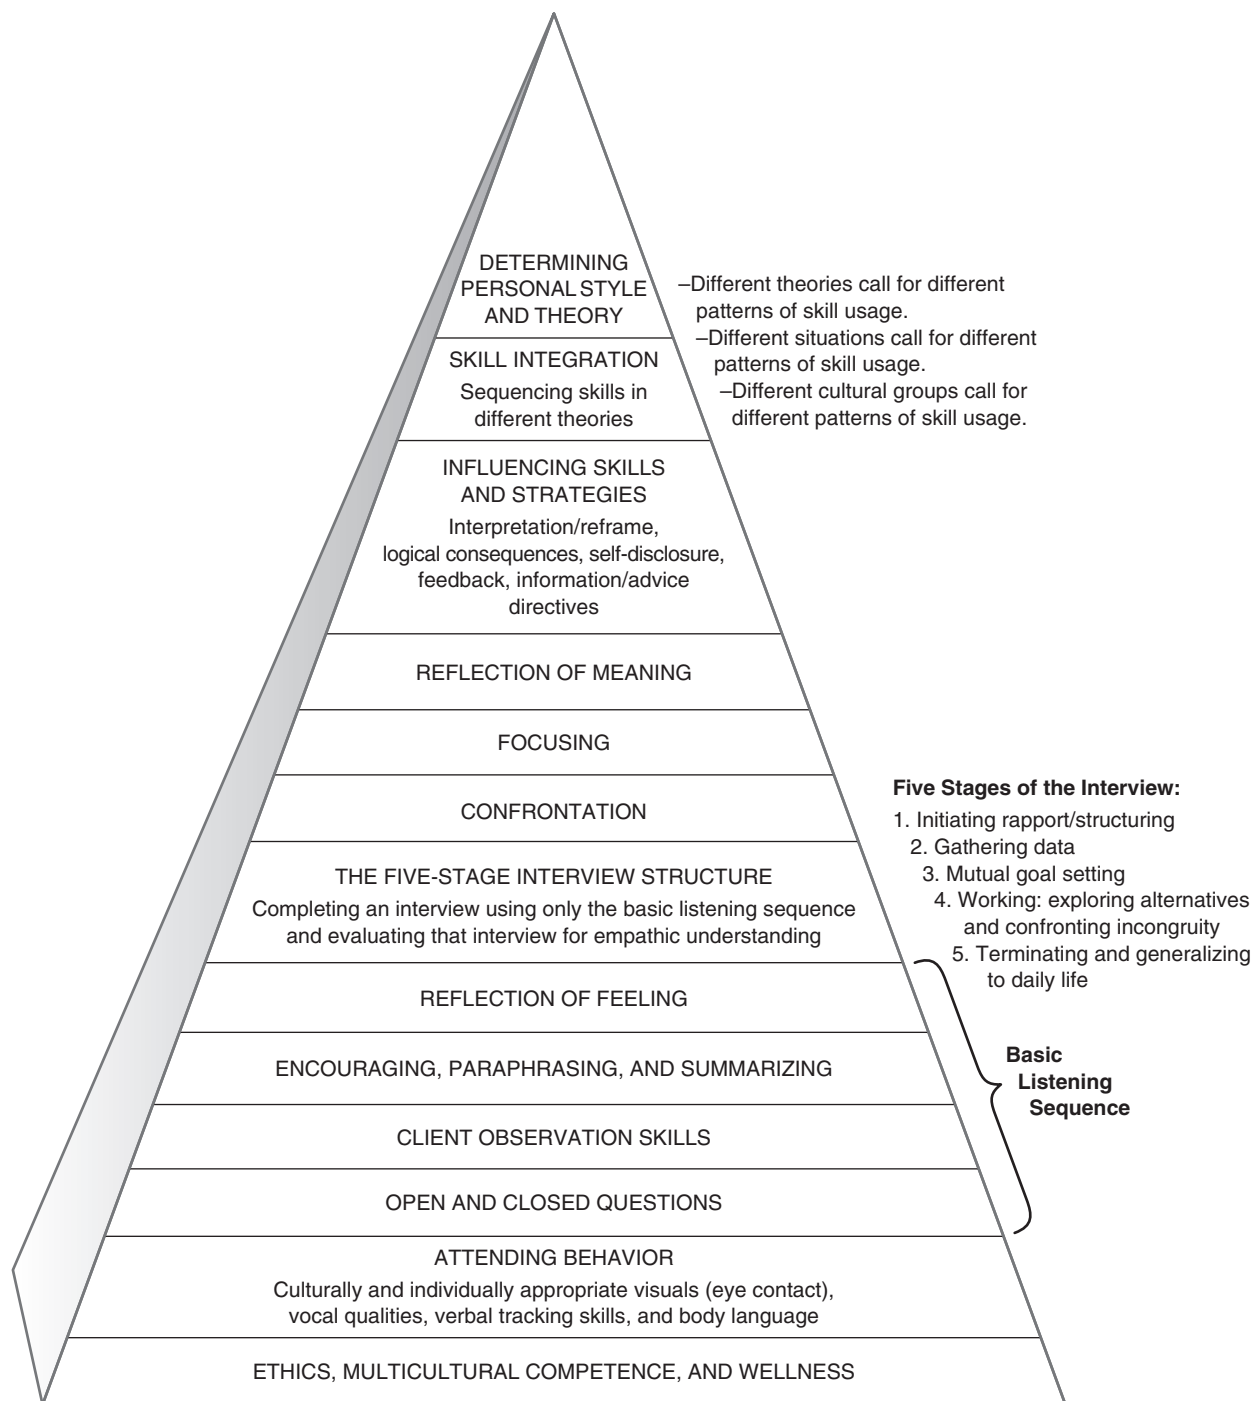

The predicted result is that clients will understand their emotional states more clearly and will correct the interviewer with a more accurate description of their emotional state if the counselor's reflection is not accurate.

### **Stages of Interview**

The microskills hierarchy proposes a five-stage organization of the interview that focuses on goals and results. The stages require that the practitioner

1. *Initiate the Session.* Establish rapport and structure the session so that clients know what to expect from the counseling or therapy process.
2. *Gather Data.* Define the problem and identify client strengths by drawing out stories, concerns, problems, or issues.
3. *Set Mutual Goals.* Determine what the client wants to happen.
4. *Explore and Create.* Generate alternatives, confront the client's conflict and incongruities, generate alternative resolutions for conflict, and help the client create a new way of thinking, feeling, or behaving.
5. *Conclude.* Plan for the generalization of the learning that has occurred in the counseling interviews to "real life" and for the eventual termination of the counseling relationship.

**Figure 1** Microskills hierarchy

Source: © 1982, 1987, 2003, 2007 Allen E. Ivey. Reprinted with permission.

The five stages may occur sequentially, particularly in decisional and career counseling, but different theories give varying attention to the skills. Brief counseling, for example, sets goals early and spends considerable time focusing on generalization

throughout the session. By way of contrast, a traditional psychoanalytic interview spends virtually the entire session focusing on the third phase of exploration of issues and concerns and gives little attention to goal setting.

Different theoretical approaches to the interview also have vastly different patterns of skill usage. For instance, practitioners of brief counseling often focus on questions, while client-centered practitioners avoid questions as much as possible and prefer reflection of feeling, paraphrasing, and summarization.

### The Multicultural Connection

In 1972, Ivey observed that Alaskan Natives had a unique pattern of eye contact and body language. Many Alaskan Natives consider direct eye contact to be rude and intrusive and, at times, consider it to be an invitation to a direct confrontation. In 1974 Ivey and Norma Gluckstern advocated the need to adopt different counseling approaches and styles with clients from different cultures.

Awareness of multicultural differences was soon expanded with awareness of the culturally unique patterns of Aboriginal Australians, African Americans, Asian Americans, Latinas and Latinos, First Nation and Native Americans, and other groups. The definition of multiculturalism was extended to include issues of gender, sexual orientation, social class, and other factors. As awareness of multicultural differences has increased over the years, the use of microskill training and theories in multicultural courses has increased to better teach students about the important individual and cultural differences that require careful attention in counseling.

### Adaptations of the Microskills Model

Multiple adaptations of the original approach to microcounseling skills are now available. For example, Gerard Egan combined the listening microskills with Carkhuff's popular model of helping. Clara Hill generated the Hill Taxonomy, a variant of the original Ivey Taxonomy of microskills, based on her extensive research coupled with her adaptation of the Egan interview structure.

The language and teaching style of the microcounseling model has become generic to the profession. Unfortunately, the culture-centered emphasis of microcounseling has not yet been generalized to the field nor to textbooks discussing counseling skills. However, guidelines for multicultural psychology have now been approved by the American Psychological Association, and the American Counseling Association has now adopted multicultural competencies, and it can be expected that counseling

skills training will eventually become more culturally sensitive.

## COUNSELING THEORIES AND THERAPIES

---

Theories and therapies of counseling are the building blocks of the profession. Probably every counselor

has had at least one course in theories of counseling, and the names of the leading theorists, such as Sigmund Freud, Albert Ellis, Carl Rogers, and others, are both legendary and familiar. This entry will address what constitutes a theory of counseling, why counseling theories and therapies are so important, and how these theories have evolved.

### Common Characteristics of Theories of Counseling

Estimates are that more than 350 counseling theories and therapies have been advanced. Although most of these have received little attention or validation, a core group of about 10 major theories, and fewer than 50 secondary approaches or modifications of the major theories, dominate the counseling profession. Most of these theories are characterized by the following important ingredients:

- A concept of how people develop throughout the life span. Typically, this involves a sequence of stages and describes important factors that are likely to influence development.
- Criteria for mental health, with characteristics of unhealthy or disordered emotional functioning either explicitly or implicitly stated. This information is important in helping people set realistic treatment goals and in assessing progress.
- Information on how to promote healthy development and help people reduce symptoms and enhance their coping skills and satisfaction with their lives.
- A description of the role of the effective counselor and the desired relationship between client and counselor. Nearly all theories of counseling currently recognize the powerful impact of the therapeutic alliance and offer clinicians ways to collaborate effectively with their clients. A safe and healing environment and a caring, skilled, and trustworthy counselor are essential to successful treatment.
- Strategies and interventions that counselors can use to help people achieve their counseling goals. Examples include reflections of feeling, modification of cognitive distortions, and systematic desensitization.
- Information on treatment parameters such as duration and frequency of sessions; whether to use individual, group, or family treatment; and benefits of medication and other adjunct services.
- Delineation of those people who are most likely to benefit from this treatment approach. This is most likely to be presented in terms of symptoms and disorders that are amenable to treatment via this approach, but might also discuss such factors as gender, age, cultural background, and other factors.

### Purposes of Counseling Theories and Therapies

Although, of course, counselors cannot master all the important counseling theories and therapies, most counselors have a few preferred theories that they use with confidence and competence. Their skills in those therapeutic approaches enable them to do the following:

- Decide whether they are likely to be able to help a particular person with a given set of concerns.
- Collaborate with clients in establishing goals that are realistic in terms of the treatment approach that is being used.
- Develop an overall plan for helping people achieve their goals.
- Individualize treatment by emphasizing and selecting interventions and strategies that are most likely to be helpful to a particular person.
- Assess a person's progress against that made by other people who received similar treatment and modify treatment if it does not seem effective.
- Deepen their knowledge of and skill in their chosen theory through experience, reading, training, and supervision.

### Four Categories of Counseling Theories and Therapies

Although counseling theories and therapies overlap considerably, they can be organized into four broad groups. Each group is characterized by its primary emphasis (background, behavior, emotions, thoughts), as well as its theoretical rationale.

#### *Theories and Therapies Emphasizing Background*

Freud, viewed as the father of psychotherapy, advanced the first widely studied theory of therapy. Although Freud's work dates back to the late 19th century, well before the advent of the counseling profession, Freud's ideas established the groundwork for all the mental health professions. Freud viewed the first 5 years of life, along with the parent-child

connection and interactions during those years, as the major determinants of a person's subsequent psychological development. Therapy sought to make the unconscious conscious and, through the transference relationship, to rectify shortcomings of the child's early connection to the parent.

Freud's followers, as well as those who later expanded and revised his concepts and strategies, include many of the early and seminal thinkers in mental health. In addition, current conceptions of brief psychodynamic therapy developed by Gerald Klerman, Hans Strupp, and others, also are rooted in Freudian thinking.

Although relatively few counselors today practice Freudian psychoanalysis, many view people from a psychodynamic perspective and believe that understanding of people's early histories is essential to their personal growth. Strategies such as interpretation, analysis of repetitive patterns, free association, exploration of transference and countertransference, modification of defense mechanisms, and discussion of early recollections all reflect the influence of Freud and others who emphasized the importance of people's history and background.

### **Theories and Therapies Emphasizing Behavior**

Theories emphasizing behavior and behavioral change represent the second wave of counseling theories and therapies. Gaining attention during the 1950s and 1960s and becoming a powerful force in the mental health professions, these approaches presented both an alternative and a challenge to psychoanalysis. Behavior therapy takes the stance that behavior is learned through exposure, modeling, conditioning, experiences, rewards, and punishments. In light of this, behavior that is unhealthy, nonproductive, or harmful to the self or others can be unlearned and replaced with new and more effective behaviors.

The foundations of behavior counseling can be found in the work of Ivan Pavlov and John W. Watson. Others, including B. F. Skinner, John Dollard and Neal Miller, Joseph Wolpe, and Albert Bandura, used both research and theory to develop strategies to promote behavioral change. More recent theorists, including Arnold Lazarus, Donald Meichenbaum, Albert Ellis, Aaron Beck, and William Glasser, have further expanded on the application of behavior counseling by combining that approach with cognitive therapy.

The popularity of solution-focused therapy also has promoted the importance and power of behavioral change.

Behavior counseling focuses on present manifestations of observable behaviors and targets a broad range of behaviors, including substance use, eating, interpersonal skills, self-care, study habits, executive functioning, exercise, parenting, working and playing, and many others. Behaviors are viewed in context and a collaborative alliance of counselor and client is viewed as essential. Treatment typically begins by establishing a baseline or clear picture of the nature and severity of the undesirable behavior. Goal setting promotes motivation, facilitates development of change strategies, and helps people move forward. Behavior counseling incorporates a wide range of strategies to facilitate change, such as education, skill training, reinforcement, desensitization, relaxation, behavioral rehearsal, and many others. Peer and group support, as well as relapse prevention, often help to solidify gains.

### **Theories and Therapies Emphasizing Emotions**

Carl Rogers, through his development of what is now called *person-centered counseling*, deserves most of the credit for bringing the third wave of counseling theories to the fore. With his emphasis on people's emotions and his deep respect for people's ability to grow and change in positive ways, Rogers humanized the counseling profession. He believed that counseling would be more effective if counselors could join with their clients on an emotional level, feel appreciation and empathy for them, help them express their emotions fully, and use their own resources to enhance their self-esteem and improve their lives. Rogers's work brought attention to the importance of the human potential and actualization, self-esteem, and the client-counselor relationship. Most counselors now appreciate the importance of the therapeutic alliance and the facilitative conditions that enhance that relationship. In addition, Rogers's deep respect for each person led to an appreciation of the importance of phenomenological approaches, those that seek to understand people's views of the world and their unique perspectives.

Although adherence to a pure person-centered treatment approach seemed to decline after Rogers's death, his emphasis on emotions had a profound impact on counseling theories and therapies. During his lifetime, other approaches emphasizing feelings, such as Gestalt

therapy, developed by Fritz and Laura Perls, and existential therapy also garnered attention. Important current treatment approaches such as narrative therapy, constructivist therapy, feminist therapy, and motivational interviewing reflect Rogers's emphasis on empathy, phenomenology, and the therapeutic alliance. These newer approaches have contributed to a deeper appreciation for the tenets of person-centered counseling.

### **Theories and Therapies Emphasizing Thoughts**

Albert Ellis, who initially developed rational emotive behavior therapy in the 1950s, led the way in the development of cognitive theories and therapies of counseling. His efforts to help people identify dysfunctional thoughts or irrational beliefs and replace them with thoughts that are valid, logical, flexible, and helpful gave counselors yet a fourth perspective on the process of change. The subsequent work of Aaron Beck provided more structure, as well as additional effective tools, to counselors who emphasized cognitions in their work.

Ellis, Beck, and other cognitive therapists hold that thoughts are the most powerful and successful route to effect change. They suggest that people's emotions and behaviors, as well as their views of the world, grow out of their thoughts and that, if they can change those thoughts in positive and healthy ways, they will be more likely to make positive changes in emotions and actions. Like behavior counseling, cognitive therapy is a structured but flexible approach that usually focuses on the present, seeks to effect fairly rapid change, and involves client-counselor collaboration. Cognitive therapy also draws heavily on a wide range of treatment strategies, such as affirmations and self-talk, thought stopping, imagery, and, most important, transformation of dysfunctional and unhealthy thoughts into healthy and helpful ones.

### **Integrated and Eclectic Counseling Theories and Therapies**

This entry on counseling theories and therapies has focused on four broad approaches to treatment, distinguished by whether they emphasize background, emotions, behaviors, or cognitions. Counselors also should keep in mind the growing trend toward eclectic and integrated approaches. Examples include Arnold Lazarus's multimodal therapy, developmental

counseling and therapy (DCT) developed by Allen Ivey and his colleagues, and the transtheoretical model developed by James Prochaska and others. Most integrated counseling theories and therapies are still in the formative stages. However, this is a growing area of the profession, and we can anticipate expansion and refinement of integrated approaches.

## **COUNSELORS AND THERAPISTS**

---

There has been considerable professional debate, in the United States and elsewhere, regarding the precise nature of the functions and roles fulfilled by counselors, therapists, psychotherapists, and others who provide mental health services. Professionals using different names, such as counseling psychologist, counselor, and therapist, are viewed quite differently by the lay public. Much of the confusion centers on *who* provides *what* services, in *what* contexts, and to *what* end or goal.

A common differentiation is that counselors concern themselves more with normative stresses, adjustment difficulties, and life transitions, whereas therapists focus primarily on mental illnesses and psychological disorders. A more comprehensive view recognizes the extensive overlap in the work of the professionals using

these designations, while, at the same time, acknowledging differences in the relative emphasis they afford to some issues. Increased clarity in this regard can facilitate an enhanced sense of professional identity for mental health practitioners and greater awareness among consumers of mental health services.

### Similarities and Differences

A crucial question underlying this issue is whether the type of work performed by the various helping professionals (e.g., counselors, therapists, and clinical social workers) is essentially the same, or whether each “camp” has a unique contribution to offer when assisting clients with their problems. There have been many attempts, at times highly politicized and market driven, to articulate the services provided by the various mental health professions. These attempts have escalated, as the historical progression of these specialties has proceeded and as these groups have sought to professionalize their services. Thus, whereas some impart a distinct meaning to the term *counseling* or *therapy*, others use the two terms more or less interchangeably.

The basic roles and functions of helping are by no means new phenomena. The desire to help others with their personal and emotional problems has a long history that can be traced to ancient western and non-western civilizations and that entails the use of very diverse methods. As noted by Colin Feltham, some of counseling’s “cousins” include advising and influencing; friendship; co-counseling; teaching and coaching; consciousness-raising; self-analysis and self-help; psychotherapy; the application of basic helping skills by social and welfare workers, probation officers, nurses, and occupational therapists; and other charismatic and fortuitous encounters (e.g., religious conversion) that may lead to healing or change. However, the more formalized or stylized practices of modern counselors and therapists have developed separately and under different sets of influences that initially shaped their functions in somewhat divergent ways.

### Perspectives Emphasizing the Distinctiveness of Counselors and Therapists

Use of the term *therapist* (or *psychotherapist*) to denote a helping relationship in the form of a “talking therapy” can be traced largely to the work of Sigmund Freud and his pioneering of psychoanalysis around

the dawning of the 20th century. Thus, therapists preceded counselors in the establishment of a professional identity and came to enjoy some recognition and status among the medical establishment of psychiatry. *Counseling*, in contrast, is a more recent label first applied to professional helping activity in the early 1900s by Frank Parsons who used it to characterize his vocational guidance movement. Then, in the 1930s and ’40s, Carl Rogers popularized the term when he sought to promote his person-centered helping techniques and to circumvent restrictions reserving the term *psychotherapist* for psychiatrists.

Because of their different origins, counselors and therapists have historically placed a different relative emphasis on certain key issues or concerns. Counseling came to be associated predominantly with the enhancement and promotion of optimal functioning and decision making among relatively normal individuals. Therapy came to be associated primarily with the remediation of actual mental illness or psychopathology. This early difference in emphasis also gave rise to a number of other perceived differences in the roles and functions of counselors versus therapists.

The work of a counselor is viewed as a shorter-term, developmental, cognitive or informational, surface-level, conscious-oriented, future-focused, acceptance-based, and positive enterprise for less-serious and extrapsychic problems. The work of a therapist, in contrast, is viewed as a longer-term, remedial, affective or emotional, in-depth, unconscious-oriented, past-focused, change-based, and pessimistic endeavor for more serious and intrapsychic issues. As suggested by the aforementioned list of adjectives, the word *counseling* is often associated with more humanistic perspectives, such as that of Carl Rogers, whereas the terms *therapy* and *psychotherapy* have sometimes been used to connote the psychoanalytic orientation of Sigmund Freud, and its derivatives. Correspondingly, therapists may be perceived as having more expertise than counselors, attributable to the common misperception that they undergo a longer and more intensive professional training that may include participating as a patient in psychoanalysis.

The recent proliferation of training programs and influx into the system of many different kinds of helping disciplines that seek professional recognition and the ability to be competitive in today’s market economy has stimulated a renewed focus on this issue. Discussions about the differences attributed to counselors and therapists have at times been framed as a

debate concerning which of the two services is more helpful, prestigious, or generally superior. Some argue that counseling is a subcomponent of the more comprehensive set of therapeutic skills, and thus counseling should be subsumed under the term *therapy*. They view counseling and therapy as lying on a continuum, with counseling representing a more circumscribed or less intense process and therapy representing a more thorough or intensive process. Others view counseling as more comprehensive than therapy because of the inclusion of specific vocational, occupational, and educational competencies in counseling training that are lacking in other training paradigms. Changes in the training of therapists and counseling psychologists and in the provision of mental health services in the last two decades render many of these issues obsolete. Nevertheless, it is likely that some associations and expectations concerning the work of counselors and therapists still persist today.

### Perspectives Emphasizing the Similarity of Counselors and Therapists

As the practice of counseling and therapy has progressed, one notable phenomenon has been the diversification of counselors into new and multiple settings, including hospitals, clinics, correctional institutions, and private practices. Some of these were previously viewed as the exclusive domain of therapists. Given these developments, many professionals today view the work of counselors and therapists as virtually indistinguishable. Recent empirical studies of the training and functions of helping professionals, the nature and severity of client issues, and the treatment goals and strategies emphasized by the practitioner reveal that there is no essential difference between what is referred to as counseling and what is referred to as therapy.

### Future Directions

It would appear that there are more similarities between the work of counselors and therapists than there are differences, and that the differences between the two are relative rather than absolute. In fact, as pointed out by J. Vincent Peterson and others, proposed distinctions between the roles of counselors and therapists are likely to be rooted more strongly in the perceptions and expectations of the corresponding professional organizations or of the general public than they are in any actual rigid state of affairs.

Although there is a strong precedent for counselors as a group to focus more on mental health and therapists as a group to focus more on mental illness, this pattern will not necessarily hold true for any given individual who identifies as a counselor or therapist.

This extensive overlap has led some leaders to call for one unified type of helping professional, often referred to as a “psychological counselor,” rather than exaggerating rather minor differences into an ever-expanding array of competing specialties and subspecialties.

## CRISIS COUNSELING

---

There are many definitions of what constitutes a crisis sufficient to bring a person to counseling. Richard K. James and Burl E. Gilliland defined a crisis as the

perception of an event or situation as intolerable and one that exceeds the immediately available resources and coping mechanisms of the person. Unless the person obtains relief, the crisis has the potential to cause severe affective, cognitive, and behavioral malfunctioning. Crisis is both universal and idiosyncratic. No matter how resilient one is, if the duration and intensity of the crisis is severe enough, no one is immune from breaking down. Crisis is also idiosyncratic because what one person may successfully overcome, another may not, even though the circumstances are virtually the same.

For most people, crises are time limited, lasting from 6 to 8 weeks. At the end of this time, people should regain a sense of equilibrium. However, this does not mean the fallout from the crisis is resolved. It simply means people should recover the capacity to function on a day-to-day basis. If resolution of the crisis does not continue or is impeded, the problems stemming from the crisis can become pervasive. The problems will change from an acute state to a chronic state wherein the individual is constantly at risk to fall back into a continuous cycle of crisis. If this happens, the person will be in a transcrisis state.

## History of Crisis Counseling

It has only been within the past 60 years that crisis intervention has grown into a field of its own with specific theories and techniques. Groundbreaking work by Erich Lindemann with the survivors of the Boston Cocoanut Grove fire of 1942 and Gerald Caplan's extension of that work forms much of the foundation for crisis intervention. Two historical events in the 1970s hallmark the birth and evolution of crisis intervention as a clinical specialty. The first was the Vietnam War and the perplexing psychological trauma that veterans carried out of it. The second was the women's movement that exposed domestic violence in its many forms. It became clear that no one is immune from the severe emotional distress and psychological disequilibrium that could result from exposure to traumatic events.

There are numerous factors that stand out as influencing the growth of crisis intervention as a clinical subspecialty.

1. *Suicide.* The possibility of dealing with suicidal clients is ever present and is prevalent in all age and racial/ethnic groups. The resulting development of

early research on the causes of suicide and suicide intervention techniques by Edwin Shneidman has been one of the seedbeds from which the fertile field of crisis intervention has grown.

2. *Crisis lines.* The advent of telephone crisis and hotlines and, recently, the Internet, has made mental health services available to vast numbers of people who would otherwise be unable or unwilling to avail themselves of mental health services. The ease of access, constant availability, lack of cost, and anonymity of the caller have made the crisis line the most used form of crisis intervention in the world.

3. *Interpersonal violence.* The discovery that more unreported or underreported interpersonal violence takes place than what was previously thought has brought this large crisis population to the attention of counselors. Interpersonal violence has far-reaching effects for the survivors that occur long past the original incident itself and form the basis for what may be called *transcrisis states*.

4. *Substance abuse and drug addiction.* The rise of substance abuse and the smorgasbord of both prescription and illicit drugs are a fertile breeding ground for personal, interpersonal, and community crisis.

5. *Posttraumatic stress disorder.* In the last four decades, posttraumatic stress disorder (PTSD) has become identified as a major mental health problem. In a world where natural disasters and human-made traumatic events occur on an everyday basis, counselors have realized that those events leave a long and wide wake of residual stress.

6. *The mentally ill on the streets.* With the advent of psychotropic drugs in the 1960s, it was believed that a significant turning point had occurred in the world of mental illness. It was felt that the antipsychotic drugs would allow the large, residential, state mental hospitals to be replaced with less-restrictive community mental health clinics and halfway houses. Unfortunately, this has not happened. The negative side effects of antipsychotic medication and the lack of adequate supervision have influenced the chronically mentally ill to stop taking their medication. Psychotic symptoms quickly resurface and are further compounded when individuals use alcohol or illicit street drugs. These "dual diagnosis" clients may then have very severe and violent psychotic breaks with reality. They also may become a large part of the homeless population. As a result, police departments have become unwilling participants

in the community mental health business as they attempt to contain these mentally ill individuals. Indeed, one of the largest groups of professionally trained crisis interventionists is specially trained police officers who operate on Crisis Intervention Teams.

## Theories of Crisis Intervention

Crisis intervention theory is in its infancy. To date, emphasis has been on helping people recover from crisis situations rather than on theory development. However, a number of experts in the field have recognized this shortcoming and are beginning to build theoretical models for understanding crisis intervention. Their research focuses on including and using contextual issues that influence individuals' reactions in crises. These researchers are integrating ideas from systems, adaptional, interpersonal, and ecological approaches to understand crisis intervention.

*Systems crisis theory* is based on the interrelationships among people and events and how they reciprocally interact with one another when a crisis occurs. The crisis of addiction, its compounding effect on the family of the addict, and the family's enabling tactics to keep the system in maladaptive homeostasis is a classic example of systems theory in operation. Crisis intervention usually means disrupting and breaking down the old system by directly confronting the behaviors that sustain it.

*Adaptional theory* operates on the premise that a crisis is sustained through maladaptive behaviors. Just as maladaptive behaviors are learned, they may be unlearned and new, more constructive behaviors that are more reinforcing to the individual may replace them. The battered wife who finally leaves the abusive relationship for a shelter, completes her education, and becomes financially and emotionally independent from her abusive and controlling spouse is an example of adaptional theory at work.

*Interpersonal theory* is based on the belief that as long as people believe that their reference of self-evaluation is placed in others, they cannot escape the crisis. By establishing or reestablishing the locus of self-evaluation within themselves, people are able to gain or regain control of their lives and take appropriate action to overcome the crisis. The grief-stricken parents of a dead child who condemn God, or the doctors, remain stuck in their grief and cannot marshal their own intrapersonal resources to overcome the traumatic event. Regaining personal control is one of

the major central axes on which crisis intervention revolves.

*Ecological theory* reaches beyond closed systems such as the family, school, or job site into the environment at large. Urie Bronfenbrenner's model for human development forms the cornerstone for this influence. Ecological theory deals with the multifaceted impact of large-scale natural and human-made disasters such as hurricanes, earthquakes, bombings, and nuclear reactor meltdowns, as well as the effects these events have not only for the people themselves, but also across the environment. Ecological theory calls for crisis intervention on a massive scale in a multitude of ways that deal with the psychological and physical needs of the survivors along with repair of the environment itself.

## Typologies of Crises

Crises can be categorized into four types. Although these overlap, each has unique characteristics setting it apart from the others. An understanding of these characteristics can increase counselors' abilities to provide the appropriate intervention.

*Developmental crises* occur when events in the normal flux and flow of human growth are disrupted by a dramatic shift that precipitates an abnormal response. Graduation from college, marriage, a first child, job change, or retirement are all key developmental benchmarks that call for dramatic shifts in how a person operates and may occasion a crisis event. Cultural variances may play a large part in whether these developmental issues are seen as crises or not.

*Situational crises* occur when an uncommon event occurs that the individual has no way of forecasting or controlling. Automobile accidents, rapes, shootings, sudden illnesses, the unexpected death of a child or spouse, job loss, and divorce are all examples of unforeseen, sudden, and intense traumatic events that are far out of the realm of normal functioning. These crises generally do not have a cultural component. The crisis of being a victim of a violent crime is a crisis regardless of the culture.

*Existential crises* are those inner conflicts that accompany the important human issues of joy, happiness, love, responsibility, goal orientation, and self-concept. Existential crises occur when individuals suddenly realize that some important intrapersonal aspect of their lives will never be fulfilled. Finding out that a major league baseball career is beyond one's

skills after a great collegiate career, never taking a risk or having an adventure before being bedridden with arthritis, and a death bed review of one's life as meaningless are examples of crises of self-purpose and self-worth.

*Systemic crises* ripple out into large segments of the population and the environment itself. Natural disasters such as Hurricane Katrina and the Indonesian tsunami wreak havoc on all parts of the ecological system across wide geographic areas. They result in death and injury, as well as the loss of basic human necessities such as food and shelter. Infrastructure services are destroyed, and the means of employment are lost because the businesses where people worked are no longer in existence. Natural and human-made disasters such as the Oklahoma City Federal Building bombing, the September 11 attacks, and school massacres not only affect the immediate victims but also psychologically impact people throughout the world via extensive media coverage. As a result, the kinds of psychological intervention applied to these crisis domains tend to be very different from those used in the normal course of psychotherapy.

### Basic Crisis Intervention

Crisis intervention targets temporary affective, behavioral, and cognitive distortions generated by traumatic events and helps people recognize and correct their perceptions, feelings, and behaviors to approximate more normal precrisis functioning. Crisis intervention is based on an equilibrium/disequilibrium paradigm that has four stages: (1) disturbed equilibrium from the trauma, (2) brief therapy targeted at the trauma and disequilibrium, (3) the client's working through the trauma, and (4) and restoration of equilibrium.

### Crisis Intervention Models

There are numerous crisis intervention models now available to the counselor. Probably the most common is the *equilibrium/disequilibrium model* that views people as in a state of disequilibrium in comparison to their precrisis coping ability. Its aim is to use previous client coping mechanisms or new counselor-generated coping mechanisms to help clients regain equilibrium and bring maladaptive responses under control. It is most often used in early intervention when the person is out of control, disoriented, emotionally distraught, and unable to function.

A specific adaption that is representative of this model for crisis intervention is a six-step model proposed by Richard James and Burl Gilliland. In this model, the steps do not necessarily function as discrete entities. Rather, some of the steps may be transposed or they may be integrated as a smoothly flowing process. Overarching the six steps is a constant and dynamic triage assessment of affective, behavioral, and cognitive functioning as proposed by Rick Myer. This continuous assessment allows counselors to evaluate the clients' past and present situational crises in regard to their ability to cope, response to personal threat, amount of lethality, degree of mobility, and type and amount of direct action needed by the counselor. The six-step model may be loosely divided into two major categories of Exploration and Acting. In the first three steps of Exploration (i.e., defining the problem, determining safety needs, and providing immediate physical and psychological support), the emphasis of the counselor will be on exploration and assessing by attending, empathizing, and being nonjudgmental, caring, respectful, and genuine. However, counselors may also become confrontive, directive, assertive, and guiding when clear threats to the client's or others' safety emerges. In the second three steps (i.e., examining alternatives, making plans, and obtaining commitment), the emphasis of the counselor will be on acting by becoming involved in the intervention at a nondirective, collaborative, or directive level according to the assessed needs of the client and the availability of environmental supports and coping mechanisms. It is likely that the second three steps will have a higher degree of counselor involvement, responsibility, information giving, guidance, and directiveness than would normally be seen in a typical counseling encounter.

### Crisis Counseling Skills

To deal with both crisis and transcrisis states calls for a variety of skills from the counselor that do not fit neatly into what might be expected of a more traditional therapist. Unlike traditional, long-term therapy, the creation of a cure or the movement of a client to more self-actualized behavior is not an end goal. The immediate and overriding objective of the crisis worker is to contain the situation, stabilize the client, stop the escalation of emotional disequilibrium and disorganization, and, it is hoped, return the client to as close to precrisis functioning as possible. Such intervention will typically be on a very time-limited basis

that may be measured in minutes, hours, or days, rather than weeks, months, or years. After stabilization, the client may be referred, if needed, to long-term therapy where systemic change and increased functioning are the goals.

The ability to use accurate listening and responding skills; assess, synthesize, diagnose, explore alternatives; and plan and solve problems are all as important in crisis intervention as they would be in traditional therapy. However, the crisis worker will typically have little time, support, or resources to do these activities. Because of rapidly changing conditions and the volatile atmosphere that surrounds a crisis, the worker will have to be exceedingly adaptive. At times, when clients are clearly out of control, crisis intervention is much more directive and closed ended than traditional therapy. It is likely that owning or "I" statements that use assertion, positive reinforcement, limit setting, and here-and-now responses are used much more than in typical counseling. The same may be said of closed questions that ask clients for "Yes" or "No" responses to determine their degree of physical mobility, psychological equilibrium, personal safety, and potential lethality towards themselves or others.

## CRITICAL INCIDENT STRESS DEBRIEFING

Critical incident stress debriefing (CISD) is a specific, seven-phase, small-group crisis intervention technique. It is a structured discussion of a significant traumatic event, commonly referred to as a *critical incident*. A critical incident stress debriefing is a supportive crisis-focused tool that is employed by a specially trained crisis intervention team after a small, homogeneous group has encountered a disturbing traumatic experience.

### The Nature of Critical Incident Stress Debriefing

#### Perspective

A critical incident stress debriefing is not a form of psychotherapy, nor does it constitute a substitute for psychotherapy. Instead, it is small group "psychological first aid." The primary emphasis in a critical incident stress debriefing is to inform and empower a homogeneous group after a threatening or overwhelming traumatic situation. A CISD attempts to enhance resistance to stress reactions, build resiliency, and facilitate both a recovery from traumatic stress and a return to normal, healthy functions.

A critical incident stress debriefing is one of many crisis intervention techniques within a larger, comprehensive, integrated, systematic, and multicomponent crisis intervention program known as *critical incident stress management*. The critical incident stress debriefing is not a stand-alone process, and it is only employed within a package of crisis intervention processes under the critical incident stress management umbrella. A CISD should be linked and blended with numerous crisis support services including, but not limited to, preincident education; individual crisis intervention; family support services; follow-up services; referrals for professional care, if necessary; and postincident education programs. Its best effects, which are enhanced group cohesion and performance, are always achieved when it is part of a broader crisis support system.

#### Historical Synopsis

Critical incident stress debriefing was developed by Jeffrey T. Mitchell in 1974 for use with small homogeneous groups of paramedics, firefighters, and

law enforcement officers who were distressed by an exposure to some particularly gruesome event. It is firmly rooted in the crisis intervention and group theory and practice of such notables as Thomas Salmon, Eric Lindemann, Gerald Caplan, Howard Parad, Lillian Rapoport, Norman Faberow, Calvin Frederick and Irving Yalom. The first article on CISD appeared in 1983.

Over time, the use of critical incident stress debriefing spread to other groups outside of the emergency services professions. The military services, airlines, and railroads find the process helpful, particularly when it is combined and linked to other crisis intervention processes. Businesses, industries, hospitals, schools, churches, and community groups eventually adopted the critical incident stress debriefing model as an integral part of their crisis support programs.

### **Objectives**

A critical incident stress debriefing has three main objectives. The first is the mitigation of the impact of a traumatic incident. The second is the facilitation of the normal recovery processes in psychologically healthy people who are distressed by an unusually disturbing event. Third, a CISD functions as a screening opportunity to identify group members who might benefit from additional support services or a referral for professional care.

### **Conditions**

The critical incident stress debriefing requires the following conditions: (1) the small group (about 20 people) must be homogeneous, *not* heterogeneous; (2) the group members must not be currently involved in the situation (i.e., their involvement is complete or the situation has moved past the most acute stages); (3) the group members should have had about the same level of exposure to the experience; (4) the group members should be psychologically ready and not so fatigued or distraught that they cannot participate in the discussion.

### **The Intervention Team**

A critical incident stress debriefing relies on a team approach. Several team members work together to conduct a CISD. One team member is required for every five to seven participants. A unique feature of

CISD is that Critical Incident Stress Management-trained peer support personnel (firefighters, paramedics, police officers, military personnel, etc.) work with a mental health professional when providing CISDs to personnel from law enforcement, fire service, emergency medical, military, medical, aviation, and other specialized professions.

## **The Critical Incident Stress Debriefing Process**

### **Timing**

The critical incident stress debriefing is often *not* the first intervention to follow a critical incident. A brief group informational process may have taken place, and distressed individuals may have been supported individually. Typically, 24 to 72 hours after the incident, the small, homogeneous group gathers for the CISD. Intervention delays may occur in disasters. Personnel may be too involved in the event to hold the CISD earlier. Depending on the circumstances, a CISD may take between 1 and 3 hours to complete.

### **Phases in the Critical Incident Stress Debriefing**

A CISD is a structured process that includes the cognitive and affective domains of human experience. The phases are arranged in a specific order to facilitate the transition of the group from the cognitive domain to the affective domain and back again. Although primarily a psychoeducational process, emotional content can arise at any time in the CISD.

#### **Phase 1—Introduction**

In this phase, the team members introduce themselves and describe the process. They present guidelines for the conduct of the CISD and motivate the participants to engage actively in the process. Participation in the discussion is voluntary and the team keeps the information confidential.

#### **Phase 2—Facts**

Only brief overviews of the facts are requested. Excessive detail is discouraged. This phase helps the participants to begin talking. It is easier for them to

speak of what happened before they describe how the event affected them. The fact phase, however, is not the essence of the CISD. The usual question is, “Can you give our team a brief overview of what happened in the situation?”

### Phase 3—Thoughts

The thought phase is a transition from the cognitive domain toward the affective domain. It is easier for people to speak of their thoughts than to focus immediately on the most painful aspects of an event. The typical question in this phase is, “What was your first thought or your most prominent thought once you realized you were thinking?”

### Phase 4—Reactions

The reaction phase is the heart of a critical incident stress debriefing. It focuses on the impact of the event on the participants. Anger, frustration, sadness, loss, confusion, and other emotions may emerge. The trigger question is, “What is the very worst thing about this event for you personally?”

### Phase 5—Symptoms

Team members ask, “How has this tragic experience shown up in your life?” or “What cognitive, physical, emotional, or behavioral symptoms have you been dealing with since this event?” The team members listen carefully for common symptoms associated with exposure to traumatic events. The team will use the signs and symptoms of distress presented by the participants as a kicking-off point for the teaching phase.

### Phase 6—Teaching

The team conducting the critical incident stress debriefing normalizes the symptoms brought up by participants. They provide explanations of the participants’ reactions and provide stress management information. Other pertinent topics may be addressed during the teaching phase.

### Phase 7—Reentry

The participants may ask questions or make final statements. The CISD team summarizes what has

been discussed in the CISD. The teams present final explanations, information, action directives, guidance, and thoughts to the group. Handouts may be distributed.

## Follow-Up

The critical incident stress debriefing is usually followed by refreshments to facilitate the beginning of follow-up services. The refreshments help to “anchor” the group while team members make contact with each of the participants.

Other follow-up services include telephone calls, visits to work sites, and contacts with family members of the participants if that is requested. At times advice to supervisors may be indicated. One to three follow-up contacts are usually sufficient to finalize the intervention. In a few cases, referrals for professional care may be necessary.

## CSIKSZENTMIHALYI, MIHALY (1934– )

---

Mihaly Csikszentmihalyi has spent his career researching creativity, happiness, subjective well-being, and fun. He is currently the C. S. and D. J. Davidson Professor of Psychology and Management at Claremont Graduate University in California. He received his Ph.D. at the University of Chicago in 1965. Csikszentmihalyi (pronounced “chick-SENT-me high”) was born in Hungary

in wartime Europe. His theories about “flow” and the psychology of optimal experience have transformed psychology as well as other fields, such as business management and leisure sciences. Csikszentmihalyi’s most important books include *Flow: The Psychology of Optimal Experience*, *Creativity*, *Finding Flow*, and *Good Business: Leadership, Flow and the Making of Meaning*.

Csikszentmihalyi’s research has had wide influence. He has served on boards and commissions such as the Department of Labor, Department of Education, and Social Science Research Council. He also has served on editorial boards and reviewed manuscripts for journals in areas such as psychology, sociology, anthropology, business management, and leisure sciences. Csikszentmihalyi has held visiting professorships in the United States, Canada, Brazil, Italy, United Kingdom, and Finland. He is also a member of the American Academy of Education, the American Academy of Arts and Sciences, the Academy of Leisure Sciences, and the Hungarian Academy of Sciences. He was the 1990 recipient of the National Recreation and Park Association’s Theodore and Franklin Roosevelt Excellence in Research Award and has received two Senior Fulbright Fellowships.

Csikszentmihalyi is well known for his forays into positive psychology and the examination of constructs like happiness, creativity, and flow. *Flow* is the term he coined to describe the state of being that results in an ardent involvement in life. Flow has been reported by people in all areas of work and leisure. It is often cultivated through artistic involvements, sports, and meditation arts, but it also can occur in work. Flow is associated with happiness and a desire for a meaningful life. People want to replicate this intrinsic mental state of flow as often as possible. Time changes, slows, and becomes different. People in flow are totally focused on what they are doing. For flow to occur, however, goals, feedback about progress toward the goals, and challenge must be appropriate to an individual’s skills. Csikszentmihalyi demonstrated how work or leisure activities that are enjoyable provide a feeling of accomplishment and competence. If a task is too easy, boredom may occur. If it is too difficult, the result is anxiety. The happiest people spend a good deal of time in a state of flow in which they are so involved in an activity that nothing else seems to matter.

## CURRENT PROCEDURAL TERMINOLOGY

---

Current Procedural Terminology (CPT) is a listing of descriptive terms and codes that are used to describe a medical procedure or service. CPT was developed and published by the American Medical Association (AMA) in 1966. The original four-digit codes were expanded to five-digit numeric (or five-character alphanumeric) codes in 1970.

The purpose of the CPT codes is to provide a uniform language that accurately describes a service (diagnostic, medical, or surgical), to serve as a method of communication among physicians, patients, and third parties.

In 1987, the Centers for Medicare and Medicaid Services (CMS), formerly the Health Care Financing Administration (HCFA), mandated that hospitals report CPT codes for outpatient hospital procedures. In August 2000, the CPT codes were named as the national standard under the Health Insurance Portability and Accountability Act of 1996 (HIPAA). Although originally designed as a form of communication, CPT codes are now used to provide the basis for physician and hospital reimbursement for outpatient hospital services received by Medicare patients.

The CPT Editorial Panel of the AMA updates the CPT nomenclature on a yearly basis to reflect

---

Current Procedural Terminology (CPT®) is copyright 2006 American Medical Association. All Rights Reserved. No fee schedules, basic units, relative values, or related listings are included in CPT®. The AMA assumes no liability for the data contained herein. Applicable FARS/DFARS restrictions apply to government use. CPT® is a trademark of the American Medical Association.

advances in medicine and technology. New CPT books are available in late fall of each year preceding their implementation, and January 1 is the effective date for using new CPT codes. Using a deleted code could cause the denial of a claim for physician or hospital outpatient services.

The Healthcare Common Procedure Coding System (HCPCS), developed by CMS in 1983 as a way to standardize the coding system used to process Medicare outpatient claims, also makes use of the CPT codes. The HCPCS has three levels, each consisting of a unique coding system. Level I is the AMA's CPT codes, and these codes make up the majority of the procedures and services performed by physicians and other health care professionals.

Level II codes are five-character codes and consist of a letter (A through V, except I and S) followed by four numeric digits. The American Dental Association owns the copyright on the "D" codes. Level II codes describe services and supplies not found in Level I codes. They include drugs, orthotics and prosthetic devices, surgical supplies, dental procedures, vision services, ambulance services, and medical equipment. Level II codes are also known as alphanumeric codes.

Level III codes are known as local codes and are assigned by local medical carriers to describe procedures and services not identified in the other two

levels. Local codes can vary from state to state. These five-digit codes begin with an alphabetic character (W through Z) followed by four numeric digits.

Category III codes, a subset of CPT, became effective in January 2001. Category III codes are temporary codes used to describe emerging technology. Category III CPT codes are alphanumeric. Category III codes are not assigned a dollar value. These codes are reported to describe new technology or new procedures that are not described by the Level I CPT codes. A procedure note is submitted to the payer when a Category III code is used. The payer will determine the appropriate reimbursement. Typically, a code is deleted after 5 years if the code has not been accepted for placement in the Category I section of CPT.

**DECI, EDWARD L. (1942– ),  
AND RYAN, RICHARD M. (1953– )**

---

Edward Deci and Richard Ryan are professors in the Department of Clinical and Social Sciences in Psychology at the University of Rochester. Their extremely productive 30-year collaboration has led to the development and continuing evolution of self-determination theory (SDT). Deci received his Ph.D. from Carnegie Mellon University in 1970, and Ryan received his Ph.D. from the University of Rochester in 1981. Their work has been focused on the effects of social contexts on motivation, particularly factors that enhance or undermine self-determination and intrinsic motivation. Together and with other collaborators, Deci and Ryan have isolated basic social cognitive processes underlying motivation. Applications of SDT have been tested in many areas dealing with parenting, sport and exercise, work, leisure, health care, mental health, education, and psychotherapy. A testament to the importance of Deci and Ryan's contributions is the substantial amount of debate and controversy that has been generated about empirical support for the theory and the implications of its various applications.

SDT is based on the assumptions that human beings actively respond to their world, are naturally inclined toward growth and development, and have a set of basic psychological needs that are culturally universal. These innate needs include autonomy, competence, and social relatedness, and their satisfaction is thought to be critical for human development and well-being. Social contexts that support the satisfaction of these

needs facilitate intrinsic motivation and consequently natural growth processes. Contexts that interfere with them are associated with poorer motivation, performance, and well-being. These contexts are characterized by external regulation that often takes the form of rewards, and since people feel controlled by rewards, these contexts can have the unintended consequence of decreasing intrinsic motivation and preventing the development of self-regulatory processes. However, Deci and Ryan have argued that even externally motivated actions can be brought under the control of self-regulatory processes if an individual engages in an active process of internalization and integration.

Since the basic psychological need for autonomy is central to effective self-regulation and well-being, autonomy is seen as being of critical importance for promoting long-term behavior change and well-being. Fostering intrinsic motivation for engaging in healthy behavior and learning in educational settings are two areas that have received a considerable amount of attention by Deci and Ryan as well as other researchers and stakeholders. SDT has been used to develop strategies to foster mental health, personal growth, and healthy behavior change in psychotherapy and population health contexts. Examples include adherence to treatment regimes for managing physical health problems, overcoming behavioral problems including abuse and eating disorders, and tackling mood disorders such as depression and phobias.

With respect to educational issues, Deci and Ryan have argued that autonomy-supportive classroom teaching approaches foster motivational styles that facilitate students' progression from an unmotivated

to a more intrinsically-motivated approach to learning. They also have addressed performance testing in schools. Although performance testing is advocated as a means of motivating students and improving school performance, Deci and Ryan have cautioned that when it is used indiscriminately it can undermine students' feelings of autonomy and a sense of personal control. Ultimately, this can lessen students' intrinsic motivation to learn, diminish their sense of well-being, and jeopardize the quality of student learning.

## DEFENSES, PSYCHOLOGICAL

---

Use of the term *defense* within psychology and counseling has a long and complex history beginning in the late 19th and early 20th centuries with the revolutionary and, at the time, controversial theoretical contributions of Sigmund Freud. Freud is considered the founder of the psychoanalytic movement within psychology and psychiatry. As theoretical advances, modifications, and challenges to the metatheory of psychoanalysis emerged through the latter half of the 20th century, this central construct of Freudian thinking evolved and developed through the works of such seminal writers as Anna Freud, Carl Jung, Heinz Hartmann, Ronald Fairbairn, Melanie Klein, Jacques Lacan, D. W. Winnicott, Otto Kernberg, and a host of other contributors to, and critics of, psychoanalytic theory.

### Basic Formulation

Psychoanalytic theory emerged onto the historical stage at the end of the Victorian era, a time that viewed human sexuality with both horror and fascination. When Freud advanced his theory of sexuality in 1905, his ideas were met with a storm of controversy, the echoes of which can still be heard today. Freud proposed that fundamental human behavior is organized largely by biological forces, chief among which is the sexual drive. Within the contemporary context of Victorian morals and mores that were predominant in Western Europe, the open expression of sexual feelings and desires was considered unacceptable in the social milieu of the time. Freud suggested that an internal war was being waged between the basic biological urge to express our sexual needs and the conservative nature of societal expectations to suppress them. Freud believed the mind generated internal psychological barriers to protect itself from the anxiety these dangerous and unacceptable sexual thoughts, images, and impulses would create if we were to become conscious of them. He called the psychological activity of building and maintaining such barriers the *defense mechanism*. In order for a defense mechanism to operate, two key functions must obtain: it must distort reality to some degree, and the psychological activity that accompanies this distortion will operate unconsciously. Freud's accompanying theory of the unconscious is perhaps his most distinctive, profound, and influential contribution to modern and postmodern thought. It is a contribution that has permeated virtually every level of philosophical, scientific, social, and popular culture.

### Post-Freudian Development of the Construct

Anna Freud, nearly as famous as her father, Sigmund Freud, made her own significant and far-reaching contribution to psychoanalytic theory by exploring the second element of her father's tripartite theory of mind, the ego. The ego houses the conscious sense of self and shapes the power of will and choice in everyday life. Key to Anna Freud's conceptualization of the ego is her elaboration of a series of psychological activities she called *ego defense mechanisms*. Although Sigmund Freud had originated the idea of the defense mechanism, Anna Freud is generally credited with the full exploration and development of this central

psychoanalytic idea. It is her work on the subject, published in 1937, which is commonly cited when referring to psychological defense.

### **Defense Mechanisms**

Anna Freud's model of psychological defense includes the following specific mechanisms: regression, repression, reaction-formation, isolation, undoing, projection, introjection, turning against the self, and sublimation. Each mechanism operates in specific ways to protect the ego from unwanted and disturbing impulses, generally thought to reflect the basic biological drives and urges including sexuality and aggression. The name of each mechanism more or less describes the nature of its operation, and these terms are familiar to many readers outside psychology and related fields. Of these, *sublimation* is a less obvious term and refers to the transformation of unacceptable impulses into socially desirable inclinations and activities. *Projection* is one of the more complex defenses in that it attributes to others various thoughts, feelings, motives, and intentions that we find unacceptable in ourselves. We may then find ourselves reacting to those attributed personality characteristics as if they originated in the other person, who, in turn may begin to counterreact in specific ways to us. Thus, a complex exchange of problematic projections, reactions, and counterreactions is created and often encountered in the therapeutic relationship.

Contemporary psychoanalytic writers have added to the list and typically differentiate defense mechanisms thought to be more primitive, including those that blatantly distort reality (such as denial), from those considered more sophisticated (such as identification, in which we model ourselves after admired or desired others). There is no "complete" list of defense mechanisms, as psychoanalytic theorists and writers continually elaborate and develop more complex models of this psychological operation. Otto Kernberg is often mentioned as one of the more influential modern psychoanalytic thinkers who contributed significantly to our understanding of personality disorders and the role played by psychological defense mechanisms in maintaining the psychopathology of those conditions.

### **Psychological Defense and the Therapeutic Process**

Although the ongoing development of the psychological defense construct has added both sophistication

and explanatory power to theoretical models, it is in the realm of the therapeutic relationship where this idea has proven to be of the greatest utility and value. Early analytic writers, following the tradition of Sigmund Freud and his immediate circle, understood the appearance of psychological defense in the course of treatment to be a manifestation of *resistance*, which is defined as the patient's reluctance to allow unconscious psychological material to enter into awareness. It was further understood that part of this resistance was also manifested in the avoidance of a deeper and more intimate relationship with the therapist through which interpretations of unconscious material might provide insight into and understanding of the patient's symptoms and behavior. It should be pointed out that even Sigmund Freud, and certainly Anna Freud, recognized that the use of psychological defenses, while by definition neurotic, was not necessarily pathological. Rather, defenses are used by relatively healthy adults as coping mechanisms for dealing with the challenges, setbacks, and disappointments that life typically provides.

It is perhaps not surprising that the ethos of Freud's time, global war, may have contributed to his conceptualization of psychological treatment as a conflict between the will of the therapist to help the patient recover and the pathological condition of the patient's will to resist that goal. In that parlance, conflict was inevitable within the therapeutic dyad and only by overcoming it could the patient find a cure for his or her psychological ills. As the utility of psychological defense as a coping mechanism became better understood and more accepted, its role in the therapeutic process also evolved.

The emergency of self-psychology, attributed primarily to the writing of Heinz Kohut, suggested the need to move away from the drive-defense model of classical psychoanalysis and to conceptualize the human psyche in more holistic and less conflict-oriented terms. Although Kohut's work is not as thoroughly covered in academic training settings as that of Sigmund Freud, he has nevertheless had a profound influence in the understanding of what occurs between client and therapist.

### **Working With the Defenses**

Recent and contemporary models of counseling and psychotherapy, even those that include a psychodynamic perspective, now tend to see the operation of psychological defense as a potential expression of the

client's need for independence, autonomy, and maintaining healthy psychological boundaries. This is not to argue that all defensive operations are healthy and appropriate, but that the therapist needs to distinguish those that require restructuring and those that are a relatively healthy expression of the client's sense of self.

Interpersonal and process-oriented psychotherapy practitioners tend to take the perspective that clients' psychological defenses are attempts to cope with the demands life is placing upon them, in the best way possible given the psychological and material resources available at that point in time. This approach provides clients with a normalizing experience of their current functioning; depathologizes, where appropriate, the choices being made; and allows for a positive self-experience through the use of healthy defenses against despair, hopelessness, shame, and guilt. As therapists work with the clients' defenses, they seek to make it safe for clients to explore alternate choices, perspectives, and perceptions in a climate of acceptance and support.

### Future Directions

Contemporary practitioners of counseling and psychotherapy have a broader range of theoretical and applied models available to them than ever before. The search for "evidence-based" or "empirically supported" treatments has encouraged practicing professionals to seek out approaches that are grounded in research and that reflect solid scientific thinking. There is a relative paucity of findings that unequivocally support the classical psychoanalytic theory of psychological defense, but the same may be said of many other current theoretical models as well. The longevity of any psychological construct is intimately connected to its utility in the practice arena. The construct known as psychological defense has demonstrated its utility across both time and theoretical formulation in explaining the vicissitudes encountered when therapist and client enter upon the healing way. From that perspective, it is likely to be with us, in some form, into the foreseeable future.

## DEMENTIA

---

*Dementia* is an inclusive term describing a group of brain disorders that cause memory loss and a decline in mental function. Researchers distinguish two types of dementia, reversible and irreversible dementia. *Reversible dementia* means the loss of memory can be cured partially or completely with treatment. *Irreversible dementia* is incurable; patients eventually become unable to take care of themselves and require 24-hour care.

Within the United States, approximately 2 million people have severe dementia, and an additional 1 to 5 million exhibit mild to moderate symptoms. Five to eight percent of people over the age of 65 have some form of dementia and the number doubles every 5 years over age 65. Up to half of those aged 85 and up are expected to contract the disease. These numbers are expected to grow as the baby boomers (individuals born between 1946 and 1964) retire and the "graying" of America accelerates.

*Alzheimer's disease* (AD; also known as *senile dementia*) is the most common form of dementia. Some of its primary hallmarks include memory loss, repeating the same thing repeatedly, having increasing difficulty naming items, and losing things or getting lost more frequently. Other signs are a change in eating habits, an abandonment of hobbies, and the loss of ability to engage in common, everyday activities. The exact causes of Alzheimer's disease are unknown, though neurofibrillary tangles and beta-amyloid plaque are hypothesized as being crucial. Other risk factors include advanced age, head injury, cardiovascular disease, renal failure, and vitamin deficiencies. Alzheimer's disease is incurable and neurodegenerative (it gets worse over time). Thus, while palliative treatments do exist, no treatment stops or reverses the progression of the disease.

The American Psychiatric Association has established two generally accepted criteria for the diagnosis of dementia, the erosion of recent and remote memory and the impairment of one or more of the following functions: language, motor activity, recognition, and executive function. The diagnosis of dementia also requires that a physician rule out the existence of delirium, a transient, acute mental disturbance that manifests as disorganized thinking and a decreased ability to pay attention to the external world.

There are three stages to Alzheimer's disease, with the first being the beginning or mild stage. In this stage, AD victims seem healthy, but they are having increasing problems dealing with life (e.g., they cannot find the right word or they engage in uncharacteristic behavior). It often takes time for an observer to realize that something is wrong because the initial Alzheimer's symptoms are often confused with changes that take place in normal aging. In the second stage, called the moderate stage, the brain becomes more damaged and problems in areas that control language, reasoning, sensory processing, and thought become more prominent. The symptoms and signs of Alzheimer's disease become more pronounced and behavioral problems can occur in this stage. In the third stage, called the final or severe stage, Alzheimer's disease sufferers may lose the ability to walk, speak, feed themselves, and recognize others.

## DEPRESSION

---

Depression is a normal human emotion that is experienced periodically in the form of "sadness," "disappointment," "grief," or being "down in the dumps." It is not uncommon to experience these feelings, particularly if environmental experiences are unrewarding, stressful, negative, or aversive. However, factors such as the frequency and duration of stressful life experiences, attribution style (or way of interpreting events), absence of environmental rewards, and a lack of coping resources influence whether these normal human experiences become symptomatic and evolve into a depressive disorder.

According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*, the two primary diagnostic criteria for major depressive disorder (MDD) are depressed mood and loss of interest or pleasure in most activities. At least one of these symptoms must occur for a duration of at least 2 weeks. Secondary symptoms include significant appetite change or weight loss or gain, sleep disturbance, psychomotor agitation or retardation, fatigue or energy loss, feelings of worthlessness or guilt, attention or concentration difficulties, and recurrent thoughts of death and/or suicide. Some depressed persons also may have psychotic symptoms (i.e., hallucinations or delusions). Typically, these symptoms are associated with increased depression severity, longer depressive episodes, and greater incapacity, and they are more resistance to treatment. The purpose of this entry is to provide information about the prevalence of depression and its effects on life functioning, risk factors associated with depression, and assessment strategies and treatment methods.

## Prevalence and Impact of Depressive Disorders

The lifetime risk of MDD is between 10% and 25% for women and 5% and 12 % for men. There is some

evidence that the incidence of depression and suicidal behavior is increasing across generations. For example, depression is now believed to be more frequent in adolescence than in adulthood. Within primary care medical settings, depression is possibly the most commonly experienced psychiatric problem. From 10% to 29% of patients in these settings have a depressive disorder and psychologists believe that clinical depression is largely unrecognized in this context.

Episodes of major depression are associated with extensive disruptions of normal functioning. These disruptions include exacerbation of medical illness and impaired physical health; diminished ability to concentrate, reason, and problem solve; decreased participation in pleasurable and rewarding activities; and problems with interpersonal relationships. The experience of a major depressive episode greatly increases the likelihood that future depressive episodes will occur. Major depression also increases vulnerability to other psychiatric problems such as anxiety disorders and alcohol abuse. The direct cost (e.g., health care and medication) of treating clinical depression is about \$400 million to \$500 million annually.

### **Risk Factors**

A variety of factors account for the greater incidence of depression observed among women relative to men. Women face different stressors (e.g., physical and sexual abuse) than men and have greater stress reactivity. They also differ in their cognitive coping styles and self-report strategies. Biological factors including increased responsiveness to hormonal changes such as those associated with the menstrual cycle and postpartum period also play a role.

Other risk factors include Caucasian ethnicity, marital separation or divorce, prior depressive episodes, poor physical health or medical illnesses, low socioeconomic status, unemployment, loss of a loved one, and family history of depression. Although major depression may develop at any age, the average age of onset is 15 to 19 years in females and 25 to 29 years for males. The average age of onset has been decreasing steadily over the past 3 decades. The elderly do not appear more susceptible to depression.

### **Assessment Strategies**

Numerous strategies have been developed to assess depression and related constructs such as attribution

style, hopelessness, and depressive vulnerability. Approaches for assessing depression include unstructured or structured interviews, self-report measures, behavioral observation, and functional analysis. The level of skill and training necessary to use these strategies is quite variable, ranging from the minimal skill required to administer and interpret a self-report measure, to the moderate skill needed to conduct and evaluate a structured interview, to the extensive skill required to perform a comprehensive functional analysis of depressive symptoms.

### ***Unstructured and Structured Interviews***

Clinical interviews include unstructured and completely flexible approaches, semistructured approaches that provide some direction while maintaining a degree of flexibility (e.g., intake form), and structured methods that are more restrictive and goal directed. Most contemporary practitioners use a combination of assessment procedures that include some type of intake form or checklist and some unstructured procedures to allow a degree of flexibility. In recent years concerns about the reliability and validity of unstructured interviews has led psychologists to place greater emphasis on more structured procedures. Among the more common structured interviews are the Structured Clinical Interview for DSM-IV—Patient Version, Anxiety Disorders Interview Schedule, Schedule for Affective Disorders and Schizophrenia, and the Hamilton Rating Scale for Depression.

### ***Self-Report Measures***

Self-report measures of depression are useful as screening instruments, as one component of a comprehensive diagnostic process, as tools for monitoring progress across treatment sessions, and as outcome measures for assessing the effectiveness of various psychosocial and pharmacological interventions. Scales are available to assess a tremendous range of content areas, including affective, verbal-cognitive, somatic, behavioral, and social symptoms of depression. At present, there are at least 80 measures designed to assess depression and related constructs, and the majority of these instruments have adequate to excellent psychometric properties. The most commonly used measures include the Beck Depression Inventories, Hamilton Depression Inventory, Center for Epidemiological Studies' Depression Scale, Harvard Department of

Psychiatry/National Depression Screening Day Scale, Reynolds Depression Screening Inventory, Minnesota Multiphasic Personality Inventory-2 Depression Scale (MMPI-2), and the Personality Assessment Inventory. All of these assessment instruments are acceptable for use in clinical practice, but the latter two are more comprehensive and more costly personality inventories.

### **Observational Methods**

Observational methods are used to measure the frequency and duration of observable behaviors that are symptomatic of depression. Some symptoms reflect behaviors that occur in *excess* of normal behavior (e.g., crying, irritation, and agitation). Others include *deficits* in normal behavior (e.g., minimal eye contact, psychomotor retardation, decreased participation in recreational and occupational activities, and disruption of sleeping, eating, and sexual behaviors).

Depressed individuals generally exhibit a slower and more monotonous rate of speech, take longer to respond to the verbal behavior of others, exhibit an increased frequency of self-focused negative remarks, and use fewer “achievement” and “power” words in their speech. Compared to nondepressed individuals, depressed individuals smile less frequently, make less eye contact, hold their head in a downward position more frequently, and are rated as less competent in social situations. Couples research suggests that when one partner is clinically depressed, interactions are more apt to involve conflict. Depressed mothers tend to be less active and playful and exhibit shorter eye-gaze durations with their children.

Several useful coding methods have been designed to assess both verbal and nonverbal behaviors. These methods will often involve video- and audiotape review, but more practically can involve direct observations in home, school, or employment contexts. Some behavioral coding systems require substantial training to achieve reliable and valid results.

### **Functional Analysis**

Functional analysis is the process of identifying important, controllable, and causal environmental factors that may be related to the etiology and maintenance of depressive symptoms. Performing a functional analysis is an essential step prior to initiating an appropriate behavioral intervention. Functional analysis involves the operational definition of undesirable

(nonhealthy) depressive behavior(s) such as lethargy, social withdrawal, crying, alcohol abuse, and suicide potential. Strategies for conducting functional analyses include interviews with the patient and significant others, naturalistic observation, and the manipulation of specific situations that result in an increase or decrease of target behaviors. Often functional analysis involves some form of daily monitoring (e.g., frequency of occurrence, the context and consequences of depressive behaviors).

When performing a functional analysis the therapist is concerned with identifying the function the depressed behavior serves for an individual (i.e., why the depressed behavior occurs). According to behavioral theory, depressive behavior occurs because reinforcement for healthy behavior is minimal or because reinforcement for depressive behavior is excessive. In other words, depressed behavior may be maintained because it leads to pleasant consequences (e.g., other people give the depressed person attention and sympathy and assume his or her responsibilities) or because it results in the removal of aversive experiences (e.g., they allow the depressed person to avoid unpleasant or stressful activities).

A functional analysis also may be performed by cognitively-oriented therapists to gain an understanding of the maladaptive thought processes they believe to be critical in eliciting depressive affect. Strategies such as thought-monitoring logs or thought-sampling methods can be used to identify the specific thought patterns elicited by certain environmental events and to determine how these cognitions correspond to depressive mood states. Behavioral interventions for depression also incorporate some form of functional analysis to help in generating specific treatment goals.

### **Treatment Strategies**

Treatment options for major depression generally include pharmacological, alternative, or psychotherapeutic approaches. Tricyclic antidepressants, monoamine oxidase inhibitors, selective serotonin reuptake inhibitors (SSRIs), and atypical antidepressants such as bupropion and venlafaxine have been shown to be effective in lessening clients' feelings of depression. In general, tricyclic antidepressants, SSRIs, and the newer atypical agents are the pharmacological treatments of choice. SSRIs and atypical antidepressants are generally preferred when they are effective because they have fewer and less aversive side effects.

For more severe depressions where other interventions have not been useful, electroconvulsive shock therapy may provide some relief. Although the evidence is unclear at this stage, alternative treatments such as St. John's Wort and omega-III fatty acids may have promise as effective treatments for clinical depression.

Psychotherapy for major depression generally includes cognitive-behavioral, problem-solving, interpersonal, supportive, psychodynamic, psychoanalytic, and couple and family approaches. Of these interventions, cognitive-behavioral, problem-solving, and interpersonal approaches have received the most support.

Research has demonstrated that both antidepressant medication and short-term psychotherapy can be effective in treating clinical depression. Some research suggests that in the short-term, antidepressant medications may be more effective than interpersonal psychotherapy or cognitive-behavioral therapy for individuals with less severe depression. Other studies suggest cognitive therapy is more effective than tricyclic medication in reducing depressive symptoms and in altering people's views of themselves, the world, and the future. Although a combined treatment might logically seem to be more effective than psychotherapy or medications alone, research has not yet demonstrated that multimodal therapy has an added benefit in treating clinical depression. However, several studies suggest this strategy may be promising among patients with more severe (chronic) depression. There are some data to suggest that depressed patients who respond to psychotherapy may be less likely to relapse following treatment termination than patients treated using only antidepressant medication.

Randomized clinical trials have been conducted to evaluate the efficacy of psychosocial interventions for depression. Using standard criteria, cognitive, behavioral, and cognitive-behavioral interventions are *efficacious* (i.e., empirically validated) and problem-solving therapy is *possibly efficacious*. It is difficult to draw conclusions about the relative therapeutic utility of these interventions, the generalizability of the findings, and the mechanisms responsible for the beneficial change. That is because researchers have used inconsistent operational definitions and measurement criteria, have provided inadequate sample descriptions, have used inappropriate statistical strategies, and have other methodological limitations.

Many factors are associated with a negative (or limited) treatment response, however, including

increased severity and chronicity of depression, family history of depression, presence of a personality disorder, coexistent Axis I conditions (e.g., anxiety disorders), perceived social stigma, increased cognitive and/or social dysfunction, marital problems, decreased treatment expectations, and double depression (or a major depressive episode superimposed on a preexisting dysthymia).

Most individuals with clinical depression receive their treatment in primary care medical settings from their primary care physicians. Many depressed individuals are undiagnosed or misdiagnosed in this setting. Furthermore, the quality of care for depression for those who are correctly diagnosed is *moderate to low* compared with that provided in more traditional mental health settings. There is minimal evidence that the specific medication prescribed is related to the treatment outcome. A more serious problem is that only 11% of primary care medical patients receive an adequate dosage and duration of antidepressant medication. Even when primary care physicians are provided with psychiatric consultations, antidepressant pharmacotherapy still is not adequately provided to a majority of patients.

In primary care medical settings, psychotherapy and pharmacotherapy have much to offer patients who are diagnosed with depression. However, these treatments either are not readily integrated into today's managed health care system, which does not support lengthier psychotherapy, or are often used inappropriately (e.g., prescription of inadequate doses of antidepressant medications). One potential solution seems to be increased use of collaborative care management programs. These programs involve an intensive primary care team (e.g., depression care manager, primary care physician, psychiatrist, and primary care expert) that provides a more integrated and effective treatment protocol to depressed patients. Given the training required to become proficient in interpersonal and cognitive psychotherapy and difficulties in administering these treatments in a time-efficient manner, the most feasible and effective psychosocial treatments for depression in primary care may be problem-solving therapy or behavioral activation. Indeed, there is no convincing research to suggest these abbreviated and more practical interventions can't address depressive symptom patterns to the same extent as more comprehensive cognitive-behavioral or interpersonal approaches.

In conclusion, depression is a prevalent and debilitating psychiatric disorder. Psychologists have a solid understanding of many of the risk factors associated

with depression and a number of effective, empirically-validated treatment strategies are available. These include cognitive-behavioral therapy, interpersonal psychotherapy, problem-solving therapy, and antidepressant medications that include tricyclic medications, SSRIs, and newer atypical antidepressants such as venlafaxine and cymbalta.

Nevertheless, many patients do not receive adequate treatment for depression in primary care settings and many patients are dissatisfied with the treatment they do receive for depression. Effective management of depressive symptoms via antidepressant medications is questionable, and antidepressants demonstrated as efficacious in clinical trials are not administered effectively under conditions of routine care. For this reason, psychotherapy for depression is preferred over pharmacotherapy in many cases. Psychotherapy appears to be equally or in some cases more effective than pharmacotherapy, and less patient relapse may occur following psychotherapy.

## DEVELOPMENTAL COUNSELING AND THERAPY

---

Developmental counseling and therapy (DCT) is a counseling approach developed by Allen Ivey for understanding and helping people. It is based in theories of individual uniqueness, human growth and development, family and environmental systems, wellness, multicultural awareness, counseling and therapy, and change. DCT may be described as an integrative metatheory that incorporates other theories and counseling approaches in a systematic manner. As a consequence, it provides a means for counselors to assess their clients accurately and choose interventions most likely to assure successful counseling outcomes.

### Human Developmental Nature

Individuals change and grow over their life span. Their unique life experiences combine to create an exclusive life story for them. That story tells how they make sense of their life experiences and transitions. How they deal with the changes and challenges of each life period becomes part of their life story. Each individual has strengths built through his or her experiences. Individuals also have some blind spots, or lack of awareness of the thoughts and feelings that keep them from living life to the fullest.

## ***Normal Development***

Basic to the DCT model is a wellness approach and a search for what is right in client development. Counselors seek to help people grow in a positive manner over the life span. Changes and transitions are normal, yet even normal changes can create difficulties. People are often confused when a transition creates conflicting emotions such as joy and sadness. This is typical because with every transition, some new and desired things are gained, and some things are lost as well. For example, the birth of a new child is a joy to parents and a cause for celebration. The birth also brings a major change in the activities of each day. "Free" time may be lost as the needs of the child require the attention of parents.

Counselors help people sort through the conflicting emotions of normal transitions and work through them successfully. Success both requires and results from one's strengths. These strengths are defined in terms of *wellness*, a holistic perspective that includes aspects of physical, emotional, social, intellectual, occupational, and spiritual health. Achieving wellness in all of these areas requires that people make intentional choices on a daily basis. Healthy choices build additional strengths for responding to life challenges.

## ***Developmental Challenges***

The challenges of life create stresses. Sometimes stresses are severe, and environmental trauma or abuse is extreme. Traditional counseling approaches view these extremes as the basis of personality disorders. From a developmental perspective, responses to trauma are normal processes of trying to make sense of one's life experiences. Trauma threatens one's sense of safety and requires defenses that match the severity of the situation. Emotional and personality disorders are thus logical responses to extreme life circumstances. For the traumatized individual, these responses are "normal."

Counselors need to understand how people make meaning of their world in order to help them grow and change. By viewing trauma responses as developmentally normal, counselors are able to focus on understanding the client rather than diagnosing a problem. This understanding is helpful for promoting a positive, proactive view of clients. It also frees clients to develop an awareness of their strengths, not just their limitations.

## **The Developmental Counseling and Therapy Model**

### ***Philosophical Foundations***

DCT is grounded in multiple theories and in the philosophical writings of Plato and the research and applications of Jean Piaget. Both proposed four levels or styles of thinking that are linear and qualitatively different.

#### ***Plato***

In the allegory of the cave, Plato explained the transition to enlightenment. A slave, chained in the dark with only candles for light, sees shadows on the walls. The slave creates stories to explain the shadows. After the slave emerges from the cave the true meaning of the shadows becomes clear. Upon returning to the cave, the shadows no longer have the same meaning. This constitutes a permanent change in perspectives and in ways of thinking. It is impossible to return to earlier stages of thinking. A "blind spot" has been removed.

#### ***Piaget***

Piaget studied the cognitive development of children and proposed four sequential stages in the development of thought processes. These stages are linear and hierarchical. They are also qualitatively different. The sensory motor stage is seen in the infant who experiences the world through the five senses: taste, touch, hearing, smell, and vision. The preoperational child begins to develop mental images to represent things that are not physically present. Lacking life experiences, these images are often incomplete or flawed. Young children, ages 7 to 11, begin to develop a concrete understanding of the world. This allows children to think logically rather than magically to explain events. Adolescents enter the final stage of development and are able to understand abstract concepts. They can imagine future events and think about and hypothesize consequences without needing to take action.

### **Four Cognitive-Emotional-Developmental Styles**

The DCT model is based in a metaphorical interpretation of the theories of Plato and Piaget. These theories propose different ways of thinking and the development of thought processes. In DCT, four

cognitive-emotional-developmental styles (CED) are defined, the sensorimotor, concrete, formal, and dialectic systemic CED styles. These are similar to Piaget's four styles but differ in that they are not linear, not hierarchical, and not sequential. They cycle over the life span in response to new developmental transitions and life experiences. The CED styles are similar to Plato's concepts in that they represent both observable external behaviors and the internal world of ideas.

Each of the four styles is a different way of processing information. An individual can function in one style most of the time or in multiple styles. The styles are not mutually exclusive and an individual can function in more than one style at the same time. Each person has a preference for a particular style in response to a given issue or set of issues. Problems arise when a person overuses one style or when he or she gets stuck in one style and is unable to see other perspectives in a situation.

The four DCT styles blend in a cyclical model and flow from one to another. An early and late component of each style contributes to the transition and flow. It is also possible to move between the styles in a nonlinear manner.

The four styles each help individuals understand their world and their experience in different and important ways. All four are important and necessary ways of understanding their experiences. The inability to function in a style is referred to as a developmental block. This is what was referred to earlier as a "blind spot." Developmental blocks can be overcome through counseling.

### ***Sensorimotor Cognitive- Emotional-Developmental Style***

Sensorimotor functioning is based in sensory experience. What one sees, hears, and feels is important. When an individual has an experience, he or she also has a feeling and feelings are based in senses. Therefore, all of one's experiences in life have a physical component. Another way to say this is that feelings are physically embedded in one's body. When an individual has an experience, he or she has a related body memory of that experience. That memory may be experienced as an image or thought.

Feelings are expressed in images that reflect conscious or unconscious thoughts. Physical sensations and feelings are the foundation of people's affective responses and often the foundation of their behaviors.

People feel and then they act. Often they are not conscious of the feelings and question why they behave as they do.

Early sensorimotor functioning is defined as the experience of feelings. Being able to locate the feelings in one's body is evidence of late sensorimotor functioning. A developmental block in this style may be either an inability to experience one's feelings or an inability to locate feelings in one's body. When individuals act in response to feelings without awareness of their feelings, they may have a developmental block in this style.

### ***Concrete Cognitive- Emotional-Developmental Style***

The concrete CED style is based in logic and details. Thinking concretely means thinking in terms of linear sequences of events. Often an individual can provide extensive detail about these events. In the early concrete stage, specific, linear details of events and circumstances are provided. The late concrete stage is characterized by if-then thinking. When an individual is able to give detailed sequences of events and reflect on those sequences, the next step is to logically see the relationship between antecedents and consequences.

Just because a person gives lots of details does not mean those details are correct or realistic. A person who leaves out important details in telling a story may have an early concrete block. Someone who is overly concrete may be able to provide many examples of overwhelming life circumstances yet be unable to understand why these events occur. This is also a block, but in the late concrete style. A late concrete block occurs when a person cannot understand relationships among events. The person cannot anticipate that *if* he or she does one thing, *then* he or she will experience a certain consequence. If the person cannot anticipate outcomes, then he or she is apt to keep repeating the same mistakes.

### ***Formal Cognitive- Emotional-Developmental Style***

The ability to think abstractly signifies formal operational thinking. In the DCT model, formal thinking means having the ability to be self-reflective and analytical. This allows an individual to see his or her patterns of thoughts, feelings, and behaviors. The individual may recognize the cause-and-effect nature

of repeating patterns as well. Repeating patterns can be positive and healthy or negative and dysfunctional.

In the early formal CED style, people become aware of their repeating patterns but may not understand how those patterns result in the problems they experience. In the late formal style, people begin to understand the patterns and the meaning those patterns have in their lives. Developmental blocks occur when a person distorts or overgeneralizes his or her patterns, or attributes causes to external events and circumstances. Distortions may occur in the area of thoughts, feelings, or behaviors, or any combination of the three. A person may have a block in the ability to see his or her patterns (an early formal block), or to understand his or her patterns (a late formal block), or both.

### ***Dialectic Systemic Cognitive- Emotional-Developmental Style***

The first three orientations in the DCT model comprise internal aspects of functioning. The fourth style, dialectic, requires that people move beyond an egocentric view to see themselves as part of multiple interacting systems. In the dialectic mode, people “think about thinking.” Their cognitive complexity allows them to view themselves and their patterns as developmentally based in family, gender, and cultural influences. They also can recognize the views of others as separate and distinct from their own.

In the early dialectic style, people are able to understand how and when their patterns developed. Typically these patterns developed in their family of origin. This understanding helps people begin to reconsider whether they want those patterns to continue. In the late dialectic style, people are able to challenge their patterns or deconstruct the meaning of the patterns. Given a choice to continue or change, a person may experience the freedom to change. Part of this awareness is the ability to understand how others think, and to recognize that not everyone thinks the same way that he or she does.

An awareness of the influence of systems and multiple interacting systems also becomes apparent in the dialectic style. An understanding of the influence of family, gender, culture, spirituality, and other multicultural factors emerges in late dialectic thinking. This understanding allows individuals to recognize how multiple systems, individually and collectively, have affected their development and continue to affect their relationships, growth, daily functioning, and holistic wellness.

A block in the early dialectic style is reflected in an inability to understand how patterns developed. Individuals may be unable to conceptualize the factors affecting their developmental processes and how those continue to influence present functioning. They also may be unable to understand or appreciate the views of others and consider that only their own perspectives are accurate. People who overuse the dialectic orientation may have a tendency to get caught up in an intellectual cloud. They may spend so much time thinking about alternatives, or who might be affected by what they do, that taking concrete action becomes difficult. They may be unable to understand the influence of one or more systems in their lives and may reject those systems as a consequence.

### **Assessing Cognitive Styles**

Ivey developed the Standard Cognitive Developmental Interview (SCDI) to facilitate exploration and movement through the four cognitive styles. This is a structured, 1 hour or more, clinical assessment during which a particular issue or presenting problem is explored in considerable depth. The assessment is unique in that it is at once an assessment, an intervention, and the foundation for treatment planning.

The purpose of the developmental assessment interview is to determine how well clients function in each of the four cognitive-emotional-developmental styles and whether developmental blocks exist in relation to specific presenting issues. The interview is always situation specific and focused on one particular issue. When multiple issues arise, successful completion of the interview depends on the ability of the counselor and client to maintain a focus rather than pursue multiple possible concerns.

The assessment process begins with the creation of an image related to the presenting issue. For example, a counselor would ask the client to think of one specific time when his or her presenting issue or problem happened. The client would then be asked to describe that time as if it were happening right now. For example, if the presenting issue was arguments with the client's spouse, the client would be asked to think of one particular argument and describe that one argument in detail. The goal in exploring the image is to help the client connect with sensorimotor experiencing in the present.

Once an affective response has occurred, movement to the concrete style is facilitated by asking the

client to provide an example of another time he or she felt the same way. After exploration of a second and sometimes third example, formal operational thinking is explored by asking for reflections on similarities or patterns between the original image and the subsequent example or examples. Movement to the dialectic style is fostered by asking the client to reflect on the origins of the pattern and on how others might view and explain the client's experiences. An important part of this process is helping clients uncover the "rule" that is guiding their behavior in the circumstances described, and that is keeping them stuck relative to their presenting issue.

Throughout the interview, it is important that counselors "stay out of the client's way" by focusing on the client's constructions of meaning. This requires the use of basic microcounseling skills such as attending, listening, paraphrasing, summarizing, questioning, and encouraging. These skills are applied within four sequences of questions corresponding to the four DCT cognitive-emotional-developmental styles. The questioning sequences, given below, are applied after the client generates an image related to a presenting issue. The image is encouraged by an open-ended question that begins with "Tell me what happens for you when you focus on [whatever issue the client has presented]."

### ***Assessing the Sensorimotor Cognitive-Emotional-Developmental Style***

Once the client has generated an image, the goal of the first questioning sequence is to help the client process the issue in the sensorimotor style and experience the issue in both the early and late sensorimotor modalities. The questions are designed to make the image present and experienced or felt in the here-and-now of the session. The following four questions are asked and considerable reflection and exploration of the client's responses is desired before moving to each new question:

What are you seeing?

What are you hearing?

What are you feeling?

Can you locate that feeling in your body?

If the client can respond positively to each of these questions, and is able to experience and explain a bodily sensation directly related to his or her feelings, an

assessment of full functioning in the sensorimotor style may be made.

If the client is unable to tell what he or she is feeling in response to the image, a sensorimotor block may be present. The presence of such a block may inhibit successful completion of the remaining portions of the interview as the embedding of the feeling is of singular importance. Should this occur, further exploration of the image with a focus on developing the image in considerable depth typically results in some type of sensorimotor experience.

The emotions expressed at this point in the interview are not necessarily highly visible and negative. Images may evoke positive feelings, and feelings may run the gamut from mild to extreme. What is important is that the client be able to describe a physical sensation in relation to the image presented, not that the counselor judge the relative importance of the feeling. When the client has reported the experience of a feeling associated with an image, and has been able to locate that feeling physically, then the counselor can summarize the first part of the interview and turn attention to the next style.

### ***Assessing the Concrete Cognitive-Emotional-Developmental Style***

The goal of the concrete questioning sequence is to determine how well the client is able to process an issue in a linear and detailed manner. The transition to this questioning sequence occurs immediately after the embedding of a feeling. It begins with a summary of the sensorimotor image, a reflection of the embedded feeling, and the question "Was there another time you felt the same way?" This question stimulates the client to determine a second example of a time when the first feeling occurred. To explore this second example, the following questions are posed:

Can you tell me specifically what happened?

What happened just before that?

What did you (or others) say (or do) when that happened?

So if you do \_\_\_\_\_, then what happens?

The counselor listens for details and for evidence of logical and if-then thinking. This questioning sequence moves the client away from present sensory experience in preparation for a more reflective style.

If a client is highly concrete and able to offer many details, multiple stories often emerge. It can be a challenge to keep this type of client focused on one story and one sequence of events. Reflecting back to the embedded feeling may be helpful. Once the concrete processing has been completed, two examples have been provided in which the same embedded feeling was predominant.

### ***Assessing the Formal Cognitive-Emotional-Developmental Style***

The transition to the formal questioning sequence begins with the summary of the first two examples. The goal is to assist the client in identifying patterns and repeating patterns by asking questions such as the following:

What similarities do you see in these two (or more) experiences?

Does this kind of thing (feeling, behavior, thought) happen a lot for you when (the situation happens)?

What are you saying to yourself when this happens?

How is your way of reacting to each situation similar?

Clients who enjoy being reflective are often easily able to see their patterns and talk about them. Clients who are not used to being self-reflective may struggle with this style. The goal is to help the client begin to relate the meaning behind his or her affective and behavioral responses to the presenting issue.

### ***Assessing the Dialectic Systemic Cognitive-Emotional-Developmental Style***

Once patterns have been identified and the meaning of the patterns has been explored, the dialectic questioning sequence may be initiated. The sequence begins with a summary of the first (sensorimotor image), second (concrete situation), and third (reflection on patterns) sections of the interview. The transition is somewhat more awkward than in the earlier parts of the interview. The first three sections are internally focused. The dialectic perspective requires that clients reflect on their situation from the perspective of others and from the lens of multiple interacting systems. For example, how are the client's reactions to his or her situation different, or not different, when interacting with family members, with coworkers in a work setting, with friends

and neighbors, or during interactions with members of a social club or religious institution. During this sequence, the counselor elicits the client's perspectives on how others might view the situation and what others might say in response to the client's concerns.

The questions are more difficult and the flow less fluid, as the client is challenged to think in new ways. Questions that may be asked in this part of the interview include:

How do you think this pattern developed (in your family or current living arrangements)?

Does this pattern happen in your family at all?

How did you learn this way of thinking and acting in your (family)?

What rule are you using when you think/act/feel this way?

The identification of a rule is perhaps the second most difficult part of the interview, after the process of embedding a feeling. Many people do not like to use the word *rule*, yet it succinctly encapsulates the issue.

The process of deconstructing or challenging the rule may be facilitated with this type of question:

I wonder if it is possible to identify any flaws in this rule, any way that following this rule keeps you from getting what you need or want?

Deconstruction is followed by directing attention to co-construction of a new rule, which leads into a commitment to continued exploration and counseling. The following two questions are asked:

As you think about it, is there a way to change this rule so you do get what you need or want?

Is this something you would like to work on in counseling?

This final question signifies both the end of the interview and the transition to a new working alliance between counselor and client. It commits the client to return for more sessions, and it sets the stage for the counselor to begin thinking about interventions.

## **Treatment Planning Using the DCT Model**

The DCT assessment interview is often a therapeutic experience that begins the change process. Identification

of the rule is tantamount to an “a-ha!” experience in which the client learns the reasons underlying automatic behaviors, or *blind spots*. Empowerment to change occurs in concert with the commitment to continue exploration in counseling. Consistent with a philosophy of wellness, clients are encouraged to make positive lifestyle choices to improve their quality of life. Such choices may occur in the physical arena, in terms of nutrition, exercise, or basic self-care activities such as tooth flossing, or in spiritual, vocational, emotional, cognitive, or intellectual areas. Personal traits such as sense of humor, sense of control, self-esteem, and rational beliefs may become the focus of wellness efforts, which are holistic and affect the total person, much as integrative counseling models address the needs of the whole person at a particular point in time.

An advantage of integrative counseling models is that they bring together assessments, interventions, and multiple theoretical approaches. What is unique about DCT is the structured manner in which the model is presented. This structure allows for virtually all counseling theories and methods to be integrated in a purposeful manner so that clinicians may use assessment results to select interventions most likely to be successful with a particular client in response to a given presenting issue. Examples of the preferred interventions based on the four styles are as follows:

*Sensorimotor*: bodywork (acupuncture, massage, yoga); catharsis; exercise (walking, jogging); focusing on emotions in the here-and-now; Gestalt interventions; guided imagery; medication; meditation; psychodynamic free association; relaxation training

*Concrete*: assertiveness training; behavioral counts and charts; brief therapy; cognitive automatic thoughts charts; crisis intervention; decision and problem solving; desensitization and establishment of anxiety hierarchies; narratives and story telling; psychoeducational skills training; reality therapy; Rational Emotive Behavior Therapy; thought stopping

*Formal*: Adlerian therapy; bibliotherapy; cognitive therapy; dream analysis; logotherapy; narratives and reflecting on stories; person-centered therapy; psychodynamic therapies; Rational Emotive Behavior Therapy

*Dialectic Systemic*: advocacy for social justice; community genograms; community or neighborhood action; consciousness raising groups; family dream analysis; family genograms; feminist therapy; multicultural counseling and therapy; self-help groups

Experienced counselors may complete the assessment within the first 100 or so words of the session as a client tells about a presenting problem. A counselor trained in DCT is usually able to determine preferred cognitive-emotional-developmental style from a short interview segment. At that point a choice may be made whether to use the assessment questions as an intervention or whether to use the information available to begin an intervention plan. As the client begins to change, intervention styles will change. An assessment of preferred style on each new issue is necessary so that optimum matching of styles and interventions may continue. Alternately, a counselor may intentionally mismatch a client's preferred style to help a client overcome a developmental block and to promote optimum development and wellness.

## Applications and Research

DCT has been used successfully with children, adolescents, and adults of all ages. It is effective and appropriate for a wide range of client populations and issues, and is useful for teaching counseling skills and for supervision in the acquisition of those skills.

## DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS (DSM)

---

The *Diagnostic and Statistical Manual of Mental Disorders*, or *DSM*, is an official classification system of mental disorders used in the United States and by many health professionals around the world. Published by the American Psychiatric Association, the *DSM* is an evolving text that is periodically revised to reflect the most contemporary knowledge regarding psychological disorders. Since its inception in 1952, this handbook has undergone a series of revisions (*DSM-II*, *DSM-III*, *DSM-III-Revised*, *DSM-IV*, and *DSM-IV-TR*).

Reflecting the human penchant for organizing and categorizing, the *DSM* contains comprehensive descriptions of several hundred psychiatric disorders, ranging from relatively minor adjustment-related issues to severe, persistent, and disabling conditions. In recent editions of the *DSM*, researchers have rigorously attempted to establish a valid and reliable diagnostic system. To this end, numerous task forces were appointed to ensure that the diagnoses reflect distinct clinical phenomena that can be applied to individuals showing a particular constellation of symptoms.

Early versions of the *DSM* were criticized for their identification with a psychodynamic theoretical orientation. The authors of recent versions purposely adopted an atheoretical approach to diagnosis, whereby descriptions of psychological disorders represent observable phenomena rather than formulations of

possible etiologies. In this respect, the *DSM* provides practitioners and researchers with a common language for delineating disorders, and it ensures that the diagnostic labels represent agreed-upon clinical phenomena.

### Epistemological Assumptions and Definition of *Mental Disorder*

The *DSM* makes the assumption that mental disorders reflect an external reality. While its creators and contributors acknowledge that mental disorders are imperfect constructions, they also posit that such constructions yield considerable practical and heuristic value (e.g., guiding clinical practice and treatment planning). To reap such benefits, the term *mental disorder* requires a meaningful operational definition. However, like many constructs in science and medicine, a consistent and all-encompassing definition remains elusive. While no definition will adequately address all elements that may distinguish abnormal from normal, the *DSM* makes a comprehensive attempt. According to the *DSM*, a mental disorder must reflect distress or disability that is present over a designated period of time and that affects the individual's life enough to create clinically significant suffering, cause a significant decrease in normal functioning, or involve serious risk to the individual. Furthermore, these experiences must not simply reflect an expectable or culturally sanctioned response to an event, such as sadness related to the death of a loved one. Finally, irrespective of their etiology, the current difficulties must be conceptualized as manifestations of personal behavioral, psychological, or biological dysfunctions.

### The Medical Model and Categorical Approach

Early in the evolution of the *DSM*, its creators attempted to establish a diagnostic system that was compatible with a broader worldwide medical taxonomy—that is, the *International Classification of Diseases, Injuries, and Causes of Death (ICD)* developed by the World Health Organization (WHO). Hence, the *DSM* adopts a medical model of diagnosis for which mental disorders, regardless of whether their etiology is biological or psychological, are viewed as “mental illnesses” requiring treatment. Furthermore, implicit in this model is the assumption that mental disorders comprise behavioral and psychological

symptoms that form a distinct and definable pattern or “syndrome.” Thus, the creators of the *DSM* made a conscious choice to adopt a categorical taxonomy of mental illnesses. It is important to note, however, that the *DSM* makes no assumption that all mental disorders are discreet entities with absolute boundaries. Rather, it adopts a prototype model with several accommodations for the “fuzzier” diagnostic situations and for within-disorder heterogeneity. These accommodations include the use of severity specifiers and subtypes, general categories for clinically significant conditions that do not meet the specifications for more specific categories (but nonetheless require clinical attention), and polythetic criteria sets whereby diagnoses are made based on a proportion of endorsed criteria out of a larger criteria set. The *DSM* has also made special efforts to increase cultural awareness and sensitivity in diagnosis by including descriptions of cultural variations in manifestations of *DSM* disorders, an appendix of known culture-bound systems that are not included in the *DSM* nomenclature, and a guide for cultural formulation.

### The Multiaxial System of Diagnosis

Over time, professionals have increasingly acknowledged that psychological disorders involve complex interactions of biological, social, and psychological factors. With this shift to a more holistic view of mental illness, or the *biopsychosocial* approach, clinicians and researchers have called for a more comprehensive approach to diagnosis. Consequently, authors of *DSM-III* accounted for this paradigm shift with the introduction of a multiaxial system of diagnosis. This system comprises five axes along which each individual is diagnostically evaluated. Each mental disorder in the *DSM* is diagnosed on either Axis I or II. The remaining three axes are used to characterize an individual's physical health (Axis III), environmental and psychosocial stressors (Axis IV), and overall level of functioning (Axis V).

#### Axis I: Clinical Disorders and “V” Codes

The major clinical disorders, or syndromes, such as depression, schizophrenia, and bipolar disorder, are diagnosed on Axis I. Axis I also includes adjustment disorders, or extreme reactions to life events that would not normally be expected (e.g., prolonged depression following the loss of a job). Also located on

Axis I are *V codes* that are used to acknowledge conditions that are not attributable to a mental disorder (e.g., academic problems, acculturation problems), but are the primary reason for seeking treatment. When these problems are evident, but not the primary focus of concern, they are noted on Axis IV.

### **Axis II: Personality Disorders and Mental Retardation**

Personality disorders and mental retardation are diagnosed on Axis II. Personality disorders reflect the presence of pervasive, inflexible, and maladaptive behaviors, thoughts, and responses that interfere with normal interpersonal relationships and cause an individual considerable distress or impairment. An example is paranoid personality disorder where an individual is significantly suspicious and distrustful of other people and interprets their intentions as threatening and malevolent. This orientation to others is often so extreme that the individual has few close relationships.

Also located on Axis II is the diagnosis of mental retardation. Although not a personality disorder, mental retardation is considered a pervasive condition that has a significant influence on a person's behavior, personality, and cognitive functioning. Of note, it is possible to have multiple diagnoses on Axis I and/or II to account for co-occurring conditions.

### **Axis III: General Medical Conditions**

Practitioners use Axis III to document any physical complaints or medical conditions that may play a role in the individual's psychological discomfort. For example, an individual suffering from panic disorder may also experience occasional asthmatic attacks in which he or she experiences respiratory distress. Given the dynamic interaction between these two experiences, it would be useful to be aware of both conditions when conceptualizing the case, developing a treatment plan, and communicating the case to other professionals.

### **Axis IV: Psychosocial and Environmental Problems**

Practitioners use Axis IV to document stressors in the environment that may aggravate, exacerbate, or in some way relate to the individual's current psychological functioning. Some examples include job loss, death of a family member, or a recent divorce.

### **Axis V: The Global Assessment of Functioning Scale**

Axis V is used to document the practitioner's overall judgment (on a scale of 1–100) of an individual's level of psychological, social, and occupational functioning.

## **DSM Assessment**

In addition to traditional diagnostic methods (e.g., clinical interviewing, objective and projective testing), several specific systems have been developed to facilitate *DSM*-based diagnosis. The most notable are the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I) and the Structured Clinical Interview for DSM-IV Axis II Disorders (SCID-II).

## **Benefits**

Although the creators of and contributors to the *DSM* acknowledge that its constructivist and categorical foundation has limitations, they also argue that it provides major benefits to the mental health field. Such benefits include (a) the promotion of effective communication among practitioners and researchers; (b) the facilitation of problem-identification, treatment, and prevention; (c) the facilitation of research into the etiology and treatment of specific mental conditions; and (d) the provision of a heuristic for teaching psychopathology and training practitioners on psychodiagnosis.

## DIALECTICAL BEHAVIOR THERAPY

---

Dialectical behavior therapy (DBT) is a cognitive-behavioral treatment program originally developed by Marsha Linehan as a treatment for highly suicidal women with borderline personality disorder (BPD) and other difficult-to-treat mental disorders. DBT draws its principles from behavioral science (e.g., reinforcement, classical conditioning), Zen mindfulness practices (e.g., quieting the mind and focusing attention), and dialectical philosophy (e.g., finding the synthesis between two differing or opposing positions). The essence of DBT as a treatment is helping the client find the synthesis of and middle path between acceptance and change. This emphasis came out of the finding that focusing solely on behavioral change or on acceptance and validation of the client's pain led to poor outcomes. Clients in DBT require a balance of acceptance and validation of their painful experiences while also working to change the behaviors and environmental factors contributing to the pain.

### Functions and Modes of DBT

DBT is a comprehensive treatment approach designed to serve five functions. First, DBT therapists help clients correct behavioral skills deficits by enhancing their capabilities. Second, motivational enhancement is generally accomplished by removing factors that detract from therapy success and increasing reinforcement of effective behaviors. A third function of DBT is to assure generalization of skillful behaviors to client's lives outside of therapy. Fourth, therapists and clients work to structure the client's environment and intervene in the world outside of therapy in ways that maximize therapy gains. Finally, to avoid therapist burnout and increase the chances of therapy being

successful, DBT serves the function of enhancing therapist capabilities and motivation.

DBT uses individual therapy, telephone consultation, therapist consultation teams, and group skills training to serve these functions. The individual DBT therapist takes primary responsibility for a client's treatment plan, progress toward therapy goals, integration of therapy modes, and management of life-threatening behaviors and crises. Individual therapy dyads engage in brief phone consultations to help the client engage in effective behavior outside of therapy sessions. DBT therapists meet as a consultation team to help one another engage in more effective treatment and to reduce burnout.

The fourth mode of DBT is skills training, which teaches clients four sets of skills. The core set of skills includes the mindfulness skills of observing, describing, fully participating, being nonjudgmental, focusing on one thing in the moment, and focusing on being effective. Interpersonal effectiveness skills include obtaining objectives, maintaining or improving relationships, and increasing self-respect in interactions. Emotion regulation skills include methods to increase positive emotions and to decrease ineffective emotional responses. Finally, distress tolerance skills include methods to help clients accept life's unchangeable and unwanted characteristics and survive crises.

### DBT Targets

DBT provides a hierarchy of treatment targets to help organize therapists' work with clients who have chaotic lives and multiple problems. Life-threatening behaviors including suicide attempts and intentional self-injury, and urges to engage in these behaviors are the highest targets. Once these objectives are obtained, the focus turns to the elimination of client and therapist behaviors that interfere with the effectiveness of therapy. The next target is behaviors that interfere with quality of life (e.g., criminal behaviors, interpersonal dysfunction, high-risk sexual behavior, or homelessness). Finally, DBT individual therapists help clients acquire skills.

Overall, the goals of DBT are to help clients replace suicidal behaviors with more effective behaviors and to help clients build lives they regard as worth living.

---

## DISCRIMINATION AND OPPRESSION

---

Discrimination and oppression are grounded in the belief of the superiority of one group over another, with corresponding rights to greater power and opportunity in society. Prejudicial feelings and beliefs are not necessarily oppressive, but frequently result in oppression when acted upon. Oppression refers to the economic, political, and cultural actions and behaviors that overpower, stifle, and exploit individuals. At the core of oppression is the unequal and often punitive use of power in society to target individuals. Justification for the abuse of power and mistreatment of individuals is found in the disparagement, vilification, and dehumanization of individuals and selected groups.

### Discrimination

Individuals and institutions discriminate when they make distinctions between people based on differences without regard to individual attributes. Discrimination is grounded in prejudice that incorporates negative attitudes or stereotypes attributed to specific groups or categories, strong emotive and affective responses to the groups, and a capacity for behavioral responses consistent with the cognitive and affective reactions towards these groups. The basis for prejudice is the belief that all individuals within a particular grouping possess equal and identical beliefs, attitudes, and abilities, and subsequently, can be expected to act and behave in predictable patterns.

*Direct discrimination* refers to the immediate experience at the point of the prejudicial act, whereas *indirect discrimination* describes the long-term effects and consequences that occur because of the direct discrimination. Discrimination promotes inequities in economic resources, educational opportunities, employment status, political power, medical access, social promotion, and cultural development.

*Reverse discrimination* is the process by which deliberate and direct policies or acts are used to benefit groups that have historically been targeted for discrimination. Also referred to as *affirmative action* and *positive discrimination*, reverse discrimination attempts to rebalance the social structure, governmental directives, and institutional policies that have promoted discrimination. However, it simply provides a possibility for greater opportunity for some traditionally disadvantaged groups and fails to address the deeply ingrained cultural and psychological factors that promote the development of prejudices and acts of discrimination within society.

### Forms of Discrimination

To fully understand the complexity of discrimination, it is essential to explore its manifestations within a multicultural society. The concept of *multiculturalism* refers to a philosophical stance that there are multiple groups in society distinguishable by many factors, including but not limited to ethnicity, class, race, gender, cultural and economic background, religion, sexual orientation, disability, and age. In a multicultural perspective, none of these factors is considered superior or inferior. However, it is common that individuals harbor preconceived notions or assumptions about divergent groups of people. These prejudices are learned through subtle and overt socialized behaviors and stereotyping. Beliefs that members of one group of people should be treated differently from members of another group lead to various forms of discrimination, often referred to as the *isms*. The more common forms of discrimination experienced in society are described in the following sections.

### Racism

Racism is the discrimination of individuals based on the belief that race is a biological factor that determines intellectual, physical, emotional, moral, traditional, and historical differences. It is a complex system

of oppression that encompasses attitudes, emotions, practices, and institutions. Intentional racism appears to date back to the beginning of the 20th century when focused attention turned to measured evaluation of superiority and inferiority among the various racial groups. An increasingly prevalent type of discrimination is *unintentional racism*, also referred to as *aversive racism*, where individuals perceive themselves as moral and good, are unaware of their biases, experience uncomfortable feelings when confronted with individuals of another race, and tend to engage in discrimination when they can rationalize their behavior as positive or “in the best interest” of the individual.

There are three distinct manifestations of racism: individual, institutional, and cultural. *Individual racism* is discrimination based on personal prejudice against specific racial groups, and ranges from deadly hate crimes and genocide at one extreme to minor acts of segregation and separation. *Institutional racism* is discrimination against individuals of color perpetuated by an organization in its policy, practice, or structure. *Cultural racism* is discrimination based on the belief that one race is superior to another, and it results in discrimination, segregation, and prejudice.

### **Anti-Semitism**

Anti-Semitism is discrimination against people of the Jewish religion, race, or ethnic background. Historically, this prejudice has ranged from individual hatred to the more organized persecution and genocide perpetrated by the Nazis. Inherent in anti-Semitism is the belief that Jewish individuals can be harmful to society and are often responsible for evils that occur in society. Anti-Semitism can be manifested in various ways, including (1) acts of hatred directed toward Jewish individuals, property, or religious institutions; (2) allegations about Jewish people that may be dehumanizing, demonizing, or stereotypical in nature; (3) hostility directed toward the state of Israel, which is seen as representative of the Jewish community; and (4) denial of the Holocaust.

### **Sexism**

Sexism refers to the discrimination of individuals based on gender. Sexism is founded in the belief that one gender is superior to the other, that there are inherent differences between the sexes that should determine gender role and opportunities in society, and feelings of

general hostility or anger toward women or men, known as *misogyny* and *misandry*, respectively. Traditional sexism focused on the inferiority of women and demonstrated overt hostility and aggression toward women. Throughout history, society has perpetuated sexist attitudes through the unequal treatment of men and women in laws, traditions, and values.

Contemporary sexism is exhibited through indifference to the inequities between men and women, and attribution of the differences based on biological and physical factors rather than social influences. Sexism is often seen on a continuum. Although there is a general understanding that women should have equal opportunity, many people still maintain the belief that gender differences are pervasive. Often they denigrate characteristics that are associated with women (e.g., emotionality, sensitivity) and attribute greater superiority to men.

### **Heterosexism**

Heterosexism refers to the discrimination of homosexuals by heterosexual individuals. There is a prominent belief in our society that the only respectable and healthy relationship is founded in heterosexuality. The heterosexual relationship, with a clear direction toward marriage, is the one that most often promotes social status and success.

Religious institutions, education, government, and society have all played a major role in forming a strong base for heterosexism. Abrahamic religions have emphasized the notion that homosexuality is contrary to natural law and is, consequently, sinful. Consequently, this view promotes the married, heterosexual relationship as the only acceptable type of relationship. Education promotes heterosexism by maintaining the heterosexual relationship as the ideal throughout the curricula and by providing little opportunity for discussion or exploration of alternative relationships. Government has also contributed to heterosexism by maintaining antisodomy laws and banning same-sex marriages in many states. These institutions work collectively to promote heterosexual relationships and provide an oppressive force against groups or practice that deviate from the norm.

### **Classism**

Classism is the discrimination against people who are perceived to be in a lower social class, frequently

indicated by a lower socioeconomic status. Classism can exist at an individual or institutional level. *Individual classism* occurs when individuals discriminate against others whom they consider to be in a lower social class, and therefore unworthy of equal respect or consideration. *Institutional classism* occurs when organizations are structured in a way that excludes or limits people from lower social classes.

Classism is based on the premise that all individuals have equal opportunity for class mobility, social progress, educational development, and economic wealth. Failing to achieve high social class status is perceived as a personal failure rather than a structured society process. Most of the focus in the literature has revolved around the issues of poverty and deficits among poor people rather than the economic, political, and psychological factors that maintain classism.

### **Colorism**

Colorism refers to the discrimination of people based on physical traits, specifically skin color, eye and hair color, hair texture, and facial features that may be reflective of a specific race or ethnic group. Slavery in the United States provided the foundations for the development of colorism. During this time, the White majority created an ideology that suggested that individuals with white skin color were the only civilized and worthy human beings and that individuals with black skin color were underdeveloped, lowly, and incapable of moral development.

Colorism has since developed to include other racial groups, such as Hispanics and American Indians, and is especially important in its impact on identity, attitudes about self, and social status. Skin tone, as related to lightness or darkness, has a profound influence on evaluations of self-worth, self-esteem, self-efficacy, and self-competence, especially among women. There appears to exist a hierarchical system where the lighter skin tone is associated with higher class status, greater physical beauty, and more privileges and opportunities.

### **Lookism**

Related to colorism, lookism is the discrimination of individuals based on a person's physical appearance, including facial expressions, clothing style, body shape or size, or perceived attractiveness. It is not related to racial or ethnic identity, but rather to physical looks, and is often perceived as one of the "more

acceptable" and "deserving" types of discrimination. In particular, weight and body size are tremendous sources of discrimination and prejudice in society, and obesity is associated with a wide variety of negative characteristics, including inability to work effectively, alienation from romantic partners and sexuality, being weak willed, and generally discontent with themselves and life.

### **Ageism**

Ageism refers to the discrimination against individuals based on their age. It is usually noted in two types: discrimination against youth and discrimination against the elderly. Ageism against the young is based in the belief that young people are irresponsible, lack maturity, exhibit poor judgment, demonstrate low impulse control, and in general, are not meriting respect equal to that of their older counterparts. On the opposite side, ageism against the elderly ranges from a general sense that older individuals are not as energetic, attractive, or competent in the workplace to more practical concerns that they merit greater benefits and compensation for their experiences. Governmental agencies have made efforts to address concerns of ageism through legislation focused on equal employment opportunities for all individuals.

### **Ableism**

Ableism is the discrimination of individuals with disabilities based on what they are able or unable to do physically and/or mentally. It originates in the belief that humans should exist without differences or disabilities and often blames the individual for his or her impairment. As such, individuals with disabilities are expected to find their own solutions to their "limitations" and society can ignore issues of accessibility and personhood. Individuals may lose status and be denied full social and economic opportunity because they are negatively evaluated.

Most countries have instituted laws that forbid discrimination based on physical or mental disabilities. These laws, more commonly referred to as *disability acts*, attempt to protect individuals' basic rights and promote equality for disabled people.

## **Forms of Oppression**

*Individual oppression* is perpetuated by one person with strong prejudicial feelings who discriminates by

utilizing personal power and status in society to oppress another. *Institutional oppression* refers to the acts of discrimination that are carried out within organizational settings with the intent and purpose of oppressing individuals and groups of people.

*Internalized oppression* is the system by which individuals maintain and identify with the oppressive conditions imposed by society. People often experience oppression at an individual and group level. These individuals frequently exhibit a sense of powerlessness, helplessness, inferiority, and degradation that hampers their efforts to liberate themselves from the internal and external oppressive forces. This is of particular concern because it results in cultural depreciation, separation from cultural identities, low self-esteem, poor identity development, and internalization of negative group identity. At the extreme, internalized oppression may lead to the disintegration of cultural development and intercultural contrast. Change to internalized oppressive forces would require challenges to the internal psychological patterns as well as the social conditions that promote oppression.

## DUTY TO WARN AND PROTECT

The *duty to warn* refers to a counselor's obligation to warn identifiable victims. The *duty to protect* is a counselor's duty to reveal confidential client information in the event that the counselor has reason to believe that a third party may be harmed. The understanding of a counselor's duty to warn begins with acknowledgment of the difference between the ethical responsibility of confidentiality and the legal term of *privileged communication*. *Confidentiality* is a demonstration of respect bestowed on the client by the counselor wherein information between the two will not be divulged by the counselor. *Privileged communication* is a legal doctrine (also known as therapist–patient privilege) that declares client–counselor therapeutic communications are to be kept private by the counselor. The client, rather than the counselor, owns this legal privilege and generally, only the client has the right to release information from the relationship. *Privileged communication* is not available in all states and it is not absolute. An exception exists, for example, when a client threatens to harm him- or herself or others. The American Psychological Association's and the American Counseling Association's Code of Ethics recognize exceptions and note that counselors are not

required to maintain confidentiality when clients pose a threat or risk to identifiable others.

The legal precedent for establishing a duty to warn and a duty to protect was set in the wrongful death case of *Tarasoff v. Regents of the University of California*. Tatiana Tarasoff was murdered by Prosenjit Poddar, a student from India enrolled at the University of California. Upon the rejection of Ms. Tarasoff's affection, Mr. Poddar became distraught and sought counseling at the university student counseling center. During therapy, the psychologist working with Mr. Poddar became concerned that Mr. Poddar intended to harm Ms. Tarasoff. The psychologist, along with a psychiatrist, unsuccessfully attempted to have Mr. Poddar committed. The psychologist also advised the campus police of his concerns. The campus police questioned Mr. Poddar, but he assured them he would not harm Ms. Tarasoff and he was subsequently released. Mr. Poddar terminated therapy and eventually went to Ms. Tarasoff's home, shot her with a pellet gun as she ran from the house, and ultimately killed her with a kitchen knife.

Ms. Tarasoff's parents filed wrongful death suits against the university as well as the psychologist and the psychiatrist because of their negligence to warn Ms. Tarasoff of the imminent danger posed by Mr. Poddar. The defendants won in the lower court, but the case was appealed and the original ruling was overturned. In overruling the lower court in 1974, the California Supreme Court issued a ruling that established a duty for therapists to warn potential third-party victims. Moreover, the California Supreme Court extended therapists' responsibility to take reasonable steps necessary to protect intended victims, thereby establishing duty to protect in the 1976 rehearing of the *Tarasoff* case. The court held that danger to the public supercedes the protective privilege of a therapeutic relationship.

The duty to warn and protect has been upheld in other states and has become the standard of practice for mental health professionals. The duty to protect continues, however, to be open for interpretation throughout the United States. In deciding whether duty to protect is present under the law, judges generally consider whether (a) there was a special relationship and the client communicated an intended threat directly to the therapist, (b) harmful action (such as severe injury, death, or psychological harm) was foreseeable and imminent, and (c) the victim

was identifiable. Different interpretations in various jurisdictions can result in apparent inconsistencies. Although many cases have issued rulings consistent with *Tarasoff*, others have resulted in rulings that allow a cause of action to a "foreseeable" victim who may or may not have been identifiable by a therapist.

### Application in the Context of Other Therapeutic Issues

The duty to warn and protect may arise in contexts other than threat of injury or homicide of identifiable victims. Counselors should be mindful of obligations to warn and protect against clients' threats of danger to identifiable or foreseeable victims of (a) HIV/AIDS, (b) child abuse or neglect, (c) incest, and (d) battery. There are also reporting considerations regarding self-injury and abortion.

Mental health professionals performing an evaluation and developing a treatment plan may be at risk for malpractice litigation when reasonable care is not exercised to prevent harm to a third party. If, in the course of developing a diagnosis or treatment plan, a counselor becomes aware of a client's physical threats to a third party, the counselor might have a duty to protect others from potential harm. An incorrect diagnosis would fall under this same guideline. For instance, if a client did not receive appropriate treatment because of an incorrect diagnosis, the client might follow through with hostile and harmful behavior. The condition of the special relationship associated with duty to protect seems to apply in both instances.

### Guidelines

There is not a simple formula to determine when the duty to warn and the duty to protect will arise, as each case is different and statutes vary among states. Generally, counselors should (a) approach potentially dangerous clients with sensitivity, (b) attend to detail and standard of care in therapeutic interventions, and (c) apply a procedure for assessing dangerousness and record-keeping. In addition, past records should be reviewed to evaluate a client's history and propensity for violence and for any other information that would give rise to a reasonable belief that the client will injure a third party. Pragmatically, counselors should obtain professional liability insurance.

### Therapeutic Considerations

Additionally, there are considerable therapeutic considerations associated with duty to warn and protect. A primary concern is client well-being. If the client turns out not to be dangerous and the counselor was insensitive in forming an assessment, the client may lose the opportunity for therapeutic intervention for long-term progress. A second therapeutic consideration is client autonomy. For example, encouraging clients to develop coping skills such as anger management could potentially serve to facilitate client self-growth and ultimately decrease the client's risk to society. A counselor has the therapeutic opportunity as well as the obligation to model socially-responsible behavior for a client who might threaten harm to others, even in a joking manner. Counselors should inform the client of the consequences of the client's intent and the necessity of the counselor to protect others.

### Steps to Follow

The following guidelines are intended to help counselors treat "potentially-dangerous" clients ethically while observing their legal obligations:

- Inform clients at the outset of and during the relationship of confidentiality limitations, and include these limitations in an informed consent document that is signed by both the counselor and the client.
- Formulate and enact steps to assess dangerousness, such as determining if the potential danger is imminent and whether a threat is to an identifiable or foreseeable victim. At a minimum, dangerousness assessment should include a history of violence (the most predictive factor), evaluation of current thoughts, and aggressive behaviors. Other risk factors include a lack of social support, mental incapacity, an organized or feasible plan for violence, and a history of substance abuse. Recognize that it is very difficult to assess homicidal intent.
- If the counselor determines imminent dangerousness, the next step is to notify the intended victim and required professionals (such as police or other authorities, Department of Health and Human Services, and 911 or any other emergency services), the necessity for whom is indicated by the case and/or the counselor's professional judgment. If possible, the counselor should decide in consultation with another qualified mental health professional precisely who should be consulted to help prevent victimization.
- Therapeutically related identified steps for counselors to protect the public include (a) increasing both the number of therapy sessions and amount of telephone contact with the client, (b) referring the client for a medical evaluation, (c) teaching anger management skills or arranging for those to be taught in individual or group settings, (d) arranging for commitment to a hospital, and (e) developing a "no-harm" contract for the client and having the client sign the contract. These steps may vary in sequence and content, depending on the circumstance of the case.
- Document (a) the justification of the decision to disclose confidential client information; (b) consultations with any necessary professionals such as psychiatrists, attorneys, law enforcement officials; and (c) any actions taken.
- Track recommendations to be certain they were followed.

Client confidentiality is generally tempered by the counselor's obligation to warn potential third-party victims. With case law varying among states, counselors must study and follow the evolving law in the state or states where they practice.

## EATING DISORDERS

---

Eating disorders (EDs) are characterized by chronicity and relapse and are some of the most common psychiatric disorders faced by girls and women. The two most common eating disorders are anorexia nervosa and bulimia nervosa. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*, the criteria for *anorexia nervosa* include emaciation (i.e., a body mass index  $\leq 17.5$ ), an intense fear of becoming fat, disturbed perception of body shape, denial of the seriousness of low body weight, and for postmenarcheal women, the absence of at least three consecutive menstrual cycles. Criteria for *bulimia nervosa* include uncontrollable binge eating followed by compensatory behavior to prevent weight gain (e.g., vomiting, excessive exercise, misuse of laxatives, fasting), occurring at least twice a week for a minimum duration of 3 months. People with anorexia or bulimia evaluate themselves primarily by their body shape and weight.

Individuals who have some, but not all, of the specific characteristics of anorexia or bulimia may meet the *DSM-IV-TR* criteria for *eating disorder not otherwise specified* (EDNOS). One example of EDNOS is binge eating disorder, which is marked by uncontrollable binge eating in the absence of compensatory behaviors. It is important to note that obesity is not recognized as an ED by the *DSM-IV-TR*, because it has not been associated with a psychological or behavioral syndrome.

## Health Risks

Disordered eating behaviors include starvation, inadequate nutrient intake, bingeing, frequent vomiting, and abusing laxatives and diuretics. These behaviors can result in numerous negative health consequences. Cardiovascular complications such as a loss of heart muscle mass, abnormal heart beat and rhythm, and cardiac failure can result from the common ED symptoms of emaciation, electrolyte disturbances, dehydration, and weight cycling. These complications can range from being relatively benign to life threatening.

Lowered bone mineral density or osteoporosis affects a large number of individuals with anorexia due to their chronic inadequate intake of nutrients such as calcium and vitamin D. Gastrointestinal difficulties such as constipation, ulcers, tears in the esophagus, and gastrointestinal bleeding can result from purging via laxatives and vomiting. Hormone functioning can be altered as a result of malnutrition and purging, which could lead to reduced fertility, increased miscarriage, and premature/underweight births. Other biochemical abnormalities from inadequate nutrient intake and purging can affect energy levels and overall physical functioning (e.g., headaches, general muscle weakness) and psychological functioning (e.g., lower well-being, elevated depression).

Individuals who chronically engage in ED behaviors are at a higher risk for these deleterious health conditions. Yet, many others participate in ED behaviors less frequently, but may still be at a significant

risk for these conditions. Periodic malnutrition (i.e., from fasting, skipping meals), electrolyte disturbances, and weight cycling are common among those who meet some, but not all, of the criteria for clinical eating disorders. This finding highlights the importance of attending to all individuals who display ED symptoms and not solely focusing on those who meet the threshold for a clinical ED diagnosis.

## The Spectrum of Eating Behavior

Eating behavior may be conceptualized along a continuum, with one pole representing clinical EDs and the opposite pole reflecting adaptive eating. The intermediate range is characterized by the use of harmful weight control strategies and food preoccupation, but at a less severe level than that of a diagnosable ED. However, because individuals in the intermediate range may jeopardize their physical and psychological health via maladaptive weight control techniques, it is crucial for counselors to focus on preventing and treating all degrees of ED symptomatology.

### *Eating Disorders and Less Severe Eating Disturbances*

Clinical criteria for EDs are quite strict. Despite a popular belief that a high percentage of adolescent girls and young adult women have bona fide EDs, only a small number are diagnosed with anorexia (0.5%), bulimia (1%–3%), or EDNOS (2%–5%). Yet, an overwhelming number of young adult women report engaging in the unhealthy weight regulation practices that fall in the intermediate category on the eating behavior continuum. In their research, Tracy Tylka and Linda Subich uncovered large percentages of high school and college women who skipped meals (59%), ate fewer than 1,200 calories a day (36.7%), eliminated fats (30.1%) and carbohydrates (26.5%) from their diet, and fasted for more than 24 hours (25.9%).

### *Adaptive Eating*

Individuals may not display ED symptomatology *per se*, but may eat maladaptively by habitually eating in the absence of hunger or eating everything on their plate with no regard to satiety level. Therefore, it is important to articulate, define, and promote adaptive eating. Studying adaptive eating is important for counselors, as it could (a) reveal how to best foster and

maintain this eating style, (b) highlight behaviors to help people strive toward in order to enhance their well-being rather than solely pinpointing maladaptive behaviors to avoid, and (c) facilitate understanding of how to prevent and treat disordered eating, as these efforts should result in an increase in adaptive eating behaviors alongside a reduction in maladaptive symptoms. Recently, Tylka supported the adaptive properties of *intuitive eating*, defined as eating in response to internal physiological hunger and satiety cues in lieu of situational and emotional cues. Although the study of adaptive eating has gained momentum, most theory and research on eating behavior has focused on ED symptomatology.

## Assessment of Eating Behavior

Eating behavior often is assessed via interviews or several psychometrically sound instruments. The Eating Disorder Examination by Christopher Fairburn and Zafra Cooper is a popular standardized interview schedule that measures dietary restraint and concern with eating, shape, and weight. Some self-report assessment instruments that measure ED symptomatology are scored according to decision rules that determine whether a person meets ED diagnostic criteria and, if so, provides the diagnosis. The Questionnaire for Eating Disorder Diagnoses (Q-EDD) by Laurie Mintz, Sean O'Halloran, Amy Mulholland, and Paxton Schneider differentiates between ED, symptomatic, and asymptomatic individuals and between those with anorexia, bulimia, and EDNOS diagnoses. The Eating Disorder Diagnostic Scale (EDDS) by Eric Stice, Christy Telch, and Shireen Rizvi diagnoses anorexia, bulimia, and binge eating disorder. A continuous ED composite score also can be calculated from the EDDS.

Other self-report instruments are scored along a gradient to reveal the degree of eating disturbance. The Eating Attitudes Test-26 (EAT-26) by David Garner, Marion Olmsted, Yvonne Bohr, and Paul Garfinkel measures dieting, bulimia, food preoccupation, and oral control and is often used as a general measure of ED symptomatology. The Eating Disorder Inventory-3 (EDI-3) by Garner measures many behavioral characteristics of EDs, such as drive for thinness and bulimia, as well as many psychological correlates of EDs (e.g., low self-esteem, perfectionism); an overall ED risk composite score can be computed. The Bulimia Test-Revised (BULIT-R) by Mark Thelen, Janet Farmer, Stephen Wonderlich, and Marcia Smith assesses levels of bulimic symptomatology. In terms of adaptive

eating behavior, the Intuitive Eating Scale (IES) by Tylka measures unconditional permission to eat, eating for physical rather than emotional reasons, and reliance on internal hunger/satiety cues to determine when and how much to eat. An overall score also can be computed.

### **Risk Factors**

There is no single cause of EDs. Rather, researchers suggest that sociocultural variables (e.g., cultural pressures for thinness), personal variables (e.g., personality, physical, behavioral, cognitive, and affective variables), and relational variables (e.g., lack of social support) are associated with the development and maintenance of eating disorders.

#### ***Sociocultural Variables***

Cultural and environmental factors that encourage individuals to focus on the appearance of their bodies in lieu of internal characteristics such as personality and intellect can lead to increased body dissatisfaction. Consequently, individuals attempt to employ maladaptive weight control strategies to conform to the cultural thin-ideal prototype. Women constitute roughly 90% of individuals with diagnosable EDs. Thus, ED symptomatology could be related to the cultural sexual objectification of women's bodies. One form of sexual objectification is the pressure to be thin that women face from family, friends, partners, and the media. Sociocultural variables are thought to play a more important role in fostering eating pathology than in maintaining it, as they are the backdrop against which individual development occurs.

In 2002, Stice conducted a meta-analysis of longitudinal studies of eating pathology. He noted that pressure for thinness leads to ED symptomatology as well as internalization of the thin-ideal societal standard, body dissatisfaction, dieting, and negative affect (i.e., a combination of anxiety, depression, and low self-esteem). He concluded that the adverse effects of pressure to be thin are more pronounced for individuals with specific maladaptive personal and relational characteristics, such as those presented next.

#### ***Personal Variables***

Stice highlighted how several personal variables may combine with other variables to increase women's

risk of disordered eating. First, elevated body mass leads to pressure for thinness and body dissatisfaction, but does not directly lead to or maintain ED symptomatology. Second, internalization of the thin-ideal societal standard leads to body dissatisfaction and negative affect, both of which lead to and maintain ED symptomatology. Third, body dissatisfaction and negative affect appear to influence each other. Fourth, maladaptive perfectionism, a personality trait characterized by unrealistically high expectations coupled with severe criticism for falling short of these expectations, leads to and maintains ED symptomatology. Although not investigated in Stice's meta-analysis, poor awareness of internal states (i.e., hunger, satiety, emotions) also has been found to contribute to ED symptomatology within several models of disordered eating.

#### ***Relational Variables***

High levels of social support from family and friends may buffer the effects of stress on ED symptomatology, as feeling accepted and appreciated by others is believed to help people feel more positively about themselves and their bodies. Therefore, low levels of social support could contribute to negative affect as well as intensify the negative effects of stress on ED symptomatology.

### **Prediction of Eating Disorder Symptomatology**

#### ***Objectification Theory***

According to Barbara Fredrickson and Tomi-Ann Roberts, sexually objectifying encounters socialize girls and women to self-objectify, or treat themselves as objects to be looked at and evaluated (e.g., by habitually monitoring their bodies and internalizing the societal thinness standard as the only attractive body type). Self-objectification, then, directly leads to consequences such as body shame and decreased awareness of internal bodily states (e.g., hunger, satiety, emotions). These consequent variables are believed to directly contribute to women's eating pathology. Many researchers have demonstrated support for the pathways of objectification theory and found that sexual objectification only influences women's ED symptomatology indirectly through its associations with personal variables (i.e., self-objectification, body shame, decreased internal awareness).

### **Dual Pathway Model**

In 1996, Stice, Carol Nemeroff, and Heather Shaw proposed the dual pathway model to explain the development of bulimic symptomatology. This model asserted that sociocultural pressures to be thin foster body dissatisfaction, as repeated messages that one is not thin enough likely encourages dissatisfaction with one's body. Internalization of the thin-ideal societal standard additionally contributes to body dissatisfaction because this ideal is difficult to attain. Body dissatisfaction in turn promotes dieting (in an attempt to achieve the thin-ideal) and negative affect (as low body esteem is equated with low self-esteem). Dieting and negative affect are the two pathways that connect body dissatisfaction to bulimic symptomatology. Dieting encourages bulimic symptomatology because the violation of strict dietary rules results in disinhibited eating, and negative affect promotes bulimic symptomatology as binge eating temporarily provides comfort and distraction from negative emotions. This model has been supported in several longitudinal studies with adolescent girls.

### **Interaction Models**

The confluence of several risk factors places individuals even more at risk for ED symptomatology. For instance, many women may experience body dissatisfaction, but of these women, only those with high levels of other variables (e.g., maladaptive perfectionism, low self-esteem, body surveillance, negative affect, or having a family member or friend with an ED) have an increased likelihood of displaying ED symptoms. These findings underscore the importance of examining how variables interact in their prediction of ED symptomatology.

## **Prevention and Treatment**

Less than 25% of individuals with EDs receive treatment; of these individuals, only 30% of clients show symptom remission that persists for at least 4 weeks. In light of the limited success in the treatment of diagnosed eating disorders, extensive efforts have been directed toward developing prevention and treatment programs designed to curb maladaptive eating practices before they develop into eating disorders. However, when evaluated (e.g., typically with female high school or college students in a school or university setting), only a few of the many extant programs

have produced lasting symptom reduction at follow-up, ranging from 1 month to 2 years.

### **Prevention of Disordered Eating**

Based on research documenting the multidimensional nature of ED risk factors, prevention programs focus on one or more of the identified risk factors. Programs that have produced lasting effects such as improvements in body dissatisfaction and amelioration of ED symptomatology typically were several hours in length (ranging from 4 to 10 hours); promoted healthy weight control behaviors, body acceptance, resistance of cultural pressures for thinness, self-esteem enhancement, and stress management; and presented information on EDs and the effects of cognitions (i.e., thoughts) on emotions. Several programs that demonstrated significant improvements had women actively challenge their beliefs about their bodies or the thin-ideal body type promoted by society. In one 4-hour program, girls who were at high-risk for ED symptomatology actively replaced their negative appearance self-statements with positive statements. Systematic desensitization (i.e., an intervention that pairs muscle relaxation with anxiety-producing objects arranged along a gradient from low to high anxiety) also was used to reduce body anxiety.

Counterattitudinal exercises in which participants actively critiqued the cultural thin-ideal body were used to reduce participants' endorsement of the thin-ideal. Women receiving this intervention showed greater reduction in ED risk factors and bulimic symptoms at the end of the program and lower binge eating through a 12-month follow-up than women who did not receive this intervention. Moreover, women in another intervention group (i.e., where a healthy-ideal weight was defined, the thin-ideal societal standard was refuted, and public commitments to follow an individualized plan that included a balanced diet and increased exercise were encouraged) achieved similar benefits.

### **Treatment of Disordered Eating**

Treatment of EDs is challenging. Clients who were once reinforced for losing weight may be reluctant to relinquish their fantasy of attaining the thin-ideal body shape. As such, many clients only enter treatment because of significant others' pleas. Clients may not yet be contemplating change.

Treatment of individuals with EDs is multidisciplinary and may involve counselors (e.g., psychologists,

social workers), physicians, and dieticians. Treatment setting is determined by the severity of ED symptomatology; medical danger from extreme emaciation or severe bingeing and purging may warrant inpatient hospitalization. Settings include outpatient treatment (e.g., weekly therapy sessions), partial hospitalization (i.e., consisting of 4–8 hours per day of treatment for 8–14 weeks), or inpatient treatment at a hospital or ED treatment facility. Regardless of the setting, intense psychotherapy and strict attention to the medical needs of the clients are imperative, and therapy may include a combination of psychoeducation (e.g., media literacy, information on healthy eating) and individual, family, and group psychotherapy. Certain antidepressant medications (i.e., Prozac) may also be used to treat bulimia and binge eating disorder, but they appear to be less effective for treating anorexia.

There are various types of psychotherapy for treating ED symptomatology. Many counselors choose to integrate aspects of these approaches and tailor the treatment to the client's individual needs. Cognitive-behavioral therapy (CBT), interpersonal therapy (IPT), feminist therapy, and family therapy are common treatment frameworks. Much empirical research has supported CBT and IPT in the treatment of ED symptomatology; more research needs to be conducted on the other approaches to determine their effectiveness.

One of the most popular approaches for treating ED symptomatology is CBT. First, in a psychoeducational component, clients are given information regarding EDs, the role of thinking in maintaining EDs, and nutrition information. They monitor their eating behaviors during this phase. For instance, individuals with bulimia may note that they binge after fasting for 8 hours. They are encouraged to begin a pattern of regular eating (e.g., three planned meals plus two or three planned snacks each day), to identify triggers for their ED symptomatology, and to generate a list of adaptive coping strategies and use these strategies (in lieu of binge or restricted eating) to deal with stress. Second, in a cognitive-restructuring phase, clients are taught to identify, question, and restructure their maladaptive general thought patterns (e.g., dichotomous, black-or-white thinking) and irrational thoughts specific to food and weight that maintain their ED and negative affect. Last, in a relapse prevention phase, clients learn how to anticipate events that may impede their continued progress and make plans to deal effectively with these events.

The focus of IPT is on addressing clients' current interpersonal relationships and how to make them

more satisfactory. The first phase is geared toward establishing rapport, explaining the treatment approach, and assessing client problem areas with careful attention to interpersonal difficulties (e.g., interpersonal deficits, grief, disputes). The second phase addresses interpersonal difficulties identified in the first phase and may include a psychoeducational component about negative affect, EDs, and how to effectively solve problems. In the last phase, clients are prepared to deal with future problems and therapeutic progress is reviewed.

Feminist therapy highlights how environmental factors such as objectification and cultural pressures to be thin contribute to ED symptomatology. After establishing an egalitarian relationship, counselors often help clients pinpoint the connection between their eating problems and the deleterious environment that maintains these problems. For instance, clients' body dissatisfaction emanating from their belief that the thin-ideal is the only attractive body shape is connected to cultural messages that espouse this unrealistic body shape. This strategy is referred to as "making the personal political." Clients are encouraged to disentangle themselves from self-objectification, and interventions are designed to foster body acceptance and appreciation by focusing on how the body functions rather than its appearance. Strategies to critically evaluate media portrayals of women and men are discussed (i.e., media literacy efforts). Assertiveness skills help clients find their voice within interpersonal encounters. Sex-role analysis helps clients identify messages they have been taught with regard to their gender that serve to maintain their ED behaviors (e.g., women should be passive and thin, men should be muscular). Clients are prompted to express their emotions within the safe therapy environment.

Because a family member's ED may be a manifestation of a problem within the entire family system, family therapy often is used to treat ED symptomatology. In structural family therapy, counselors focus on identifying roles, alliances, conflicts, and interaction patterns within the family that are related to the ED. Once these patterns are acknowledged, counselors tailor their interventions to facilitate appropriate and healthy expression from each family member and enhance the well-being of the entire family system.

## Future Directions

Most theory and research on ED symptomatology has focused on women who are young, Caucasian, and

heterosexual. As a result, ED symptomatology may be different for other individuals and therefore not reflected in *DSM-IV-TR* criteria for EDs. For instance, anorexia is much less prevalent among men than women, and only about 10% of the individuals with bulimia are men. Yet, one third of all men desire a leaner body and approximately one quarter of all men want a more muscular body. Some of these men may internalize environmental pressures to become more muscular, become dissatisfied with their bodies, and go to extreme efforts to gain muscle mass by using anabolic steroids and eating maladaptively (e.g., eating excessive amounts of protein, becoming preoccupied with eating 20 grams of protein in 2-hour intervals). Indeed, contemporary American men display substantial body dissatisfaction, which is often expressed as muscle belittlement (i.e., believing they are less muscular than they are). This dissatisfaction is closely associated with depression, ED symptomatology, use of performance-enhancing substances, and low self-esteem.

Although body dysmorphic disorder may reflect men's muscle dysmorphia, the associated maladaptive eating behaviors are not recognized in the *DSM-IV-TR*. This neglect has clinical implications, as it may lead to counselors overlooking these deleterious behaviors in their clients. Furthermore, because many ED instruments were designed to assess only diagnostic criteria for EDs and not other maladaptive eating behaviors, counselors may miss maladaptive eating behaviors when they exist, leading to some clients not being appropriately identified or treated for an eating disturbance.

Future efforts also need to be directed toward exploring extant models of ED symptomatology with diverse samples and developing models that more appropriately reflect the experiences of other groups of individuals. Ethnic identity (e.g., expressing positive ethnic attitudes; identification with, affirmation of, and belonging to an ethnic group) has been asserted to protect individuals of color from internalizing Western cultural standards of attractiveness and developing body dissatisfaction and ED symptomatology. However, preliminary findings suggest that a strong ethnic identity may not directly protect women of color from internalizing the Western thin-ideal body type, having a negative body image, or displaying ED symptomatology. Instead, ethnic identity appears to positively influence the self-esteem of women of color, and self-esteem then protects these women from

internalizing the thin-ideal body type, body dissatisfaction, and ED symptomatology.

## EGO STRENGTH

---

The concept of ego strength derives from psychoanalytic theory and refers to the healthy, adaptive functioning of the *ego* (i.e., the capacity for effective personal functioning). Sigmund Freud conceptualized the ego as an intrapsychic substructure that serves the essential organizing and synthesizing functions that are necessary for an individual to adapt to the external world. When the ego performs these functions adequately (Table 1), individuals experience themselves as coherent, functional human beings with an enduring sense of personal identity. They are said to possess *ego strength*.

### Intrapsychic and Interpersonal Dimensions

Ego strength has both intrapsychic and interpersonal dimensions. It implies a composite of internal psychological capacities—both cognitive and affective—that individuals bring to their interactions with others and with the social environment. Ego strength reflects a person's capacities for adaptability, cohesive identity,

personal resourcefulness, self-efficacy, and self-esteem. Ego strength also connotes mental health as encapsulated in Freud's well-known phrase “to love and to work.” Indicators of ego strength include interpersonal competence, a sense of purpose, life satisfaction, and the capacity for meaningful activity. Like the solid foundation of a well-built house, ego strength supports the individual across developmental stages in the pursuit of life goals, dreams, and ambitions, especially under stressful conditions or during turbulent times. Ego strength provides an individual with a cohesive sense of self, ensures coping abilities, increases as individuals grow in maturity, and is recognizable during initial clinical assessment and throughout psychotherapy.

### Utility and Relevance

The importance of ego strength as an area for clinical assessment derives from the notion that the significant problems in living for which people seek therapeutic assistance often express themselves as *ego deficits* (i.e., a lack of ego strength). Deficits in ego strength can manifest as poor judgment, difficulties with reality testing, and problems with interpersonal relationships or intimacy. A lack of ego strength can also show in extreme defensiveness, lack of self-control, and the inability to regulate emotions or self-soothe when distressed. Ego deficits are also apparent in the individual with poor self-esteem, no cohesive identity, unrealistic or inconsistent life goals, and issues with mastery and competence.

Psychotherapists pay special attention to ego strength when assessing a client's current capacities and potential to benefit from therapy. Their ability to support a client's current and developing ego strength depends on their ability to identify and assess ego functions in the clinical situation. In psychoanalytic theory, a client can grow in ego strength over time by identifying with and incorporating the therapist's own ego strength. Across mental health practice disciplines, clinicians assess ego strength to locate a client on a developmental continuum. That allows them to identify a suitable place to begin therapeutic work, provides data to develop therapeutic goals, and constitutes a baseline against which to measure psychotherapeutic progress.

### Historical Perspective

#### *Structural Theory*

Freud's conceptualization of the ego took shape around the turn of the 19th century. Freud was deeply

**Table 1** Ego functions

<i>Ego Function</i>	<i>Client Description</i>	<i>Sample Assessment Item</i>
Reality testing	Distinguishes between inner and outer stimuli	Explains problems by means of false beliefs or control by a supernatural power
Judgment	Aware of appropriateness and likely consequences of intended behavior	Makes foolish, poorly considered, or bad decisions
Sense of reality of the world and self	Experiences external events as real; differentiates self from others	Able to look realistically at his/her good and bad qualities
Affect and impulse control	Maintains self-control; can tolerate intense affect and delay gratification	Gets upset or loses control when dealing with strong feelings
Interpersonal functioning	Sustains relationships over time despite separations or hostility	Seems to just use people to get the things he/she needs
Thought processes	Attention, concentration, memory, language, and other cognitive processes are intact; thinking is realistic and logical	Seems weird, bizarre, or out of touch with reality
Adaptive regression	Relaxes ego controls, allowing creative integrations to increase adaptive potential	Recovers from emotional upset quickly, with previous capacities intact or improved
Defensive functioning	Defenses satisfactorily prevent anxiety, depression, and other unpleasant affects	Explains his/her problems as caused entirely by others
Stimulus barrier	Aware of sensory stimuli without stimulus overload.	Easily overwhelmed by too much activity or interaction with others
Autonomous functioning	Cognitive and motor functions (primary autonomy) and routine behavior (secondary autonomy) are free from disturbance	Structures his/her own time and enjoys it
Synthetic-integrative functioning	Able to integrate contradictory attitudes, values, affects, behavior, and self-representations	Believes he/she is a good person, worth caring about, but with some problems
Mastery-competence	Performance is consistent with existing capacity	Lives up to his or her potential and feels good about his/her work

Source: Adapted from Bellak (1989).

pessimistic about human nature and impressed with the archaic drives and primitive passions that seemed to shape human behavior. He came to understand civilized, adult behavior as the end result of the ego's

struggle to mediate between the powerful, infantile, even bestial forces of the *id* and the punitive requirements of the *superego* for social conformity. The ego of Freud's structural theory lacked strength relative to

the id. His metaphor for the ego was a person on horseback who can barely hold in check the superior strength of the horse. Freud did not recognize the fullness of an ego that, in addition to its job of holding id impulses in check, performs other vital functions, including perception, cognition, judgment, reality testing, and affect regulation.

## **Ego Psychology**

Colleagues who carried Freud's structural theory forward in the first decades of the 20th century did so in the context of a devastating First World War, the deadly flu pandemic of 1918, and the destruction of the Austro-Hungarian empire. That historical era was followed by the Great Depression, the rise of Nazism, the earliest days of the Holocaust, and the burgeoning militarism that culminated in World War II. In contrast, ego psychology was elaborated during the more optimistic post-World War II era by European expatriates who emigrated to the United States to escape Nazi persecution. They shared Freudian beliefs about the power of the id and its biological drives but, buoyed by the political freedom and optimism of American society, they were far more interested in the ego and its functions. In particular they focused on how ego functions contributed to the unfolding of human capacities in response to the interaction between environmental factors and innate potentials. The psychoanalyst Heinz Hartmann was the first to suggest that some ego functions are independent of, and autonomous from, the drives (id). Since this seminal contribution, many others have elaborated ego psychology, most notably Erik Erikson, who proposed an enduring stage theory of ego development over the life span.

## **Assessing Ego Strength**

### **Ego Function Assessment**

The most comprehensive and systematic effort to describe and study ego functions, whose healthy adaptations essentially constitute ego strength, has been undertaken by Leopold Bellak and colleagues. Beginning in 1958, Bellak began to study the nature of the psychoanalytic process in a controlled, experimental way. His National Institute of Mental Health (NIMH) research study resulted in a list of 12 ego functions considered necessary and sufficient to describe the personality of the individual. The list is a

useful outline for assessing a person's strengths or evaluating therapeutic gains.

### **Other Approaches to Ego Strength Assessment**

An alternative approach to assessing ego strength involves ego-oriented assessment as a process of data collection over several interviews on a client's current and past functioning and on his or her inner capacities and external circumstances. Questions that guide the overall assessment of ego strength include:

1. To what extent is the client's problem a function of
  - stressors imposed by his or her current life roles or developmental tasks?
  - situational stress or a traumatic event?
  - impairments in his or her ego capacities?
  - developmental difficulties or dynamics?
  - the lack of environmental resources or supports?
  - a lack of fit between his or her inner capacities and external circumstances?
2. What inner capacities and environmental resources does the client have that can be mobilized to improve his or her functioning?

Ego strength assessment is not essential to all forms of help giving, but it can help determine where to direct interventions. For example, in some cases it is important to maintain, enhance, or modify inner capacities. At other times intervention is designed to mobilize, improve, or change environmental conditions. Sometimes intervention is necessary to improve the fit between inner capacities and external circumstances. When a client is overwhelmed by current stressors but evidences some ego strength and has at least some environmental supports, the practitioner will use a supportive approach aimed at stress reduction and more effective problem solving. In contrast, clients who have limited ego strength and developmental deficits that interfere with their ability to cope with current life roles need interventions targeted at building ego strength.

## ELLIS, ALBERT (1913–2007)

---

Albert Ellis, the developer of *rational emotive behavior therapy* (REBT), contributed greatly to the practice of psychotherapy through his clinical practice, involvement with numerous professional organizations, publications of books and articles, and teaching. Ellis was born in Pittsburgh and was raised in New York City. He had a difficult childhood and, due to the family discord, focused his attention toward books and understanding others. In junior high school, Ellis planned to study accounting. Experiencing the Great Depression, however, altered this goal and he graduated from college in 1934 with a degree in business administration from the City University of New York. In 1942, he returned to school, entering the clinical psychology program at Columbia. He started a part-time private practice in

family and sex counseling soon after he received his master's degree in 1943. Ellis earned his Ph.D. in clinical psychology from Columbia in 1947. He had been trained in psychoanalysis as the primary form of treatment and he entered into a training analysis program with the Karen Horney group. Ellis completed the full analysis and began practicing classical psychoanalysis. During this time, Ellis taught at Rutgers and New York University and was the senior clinical psychologist at the Northern New Jersey Mental Hygiene Clinic. He also became the chief psychologist at the New Jersey Diagnostic Center and then at the New Jersey Department of Institutions and Agencies.

Although trained in psychoanalysis, Ellis experienced frustration when his patients showed only moderate improvement when he worked with them from a psychoanalytic orientation. He observed that when he saw clients once a week or even every other week, they progressed as well as when he saw them daily. Ellis found that patients seemed to improve more rapidly when he was active and direct in his methods. The perceived lack of efficacy of psychoanalytic treatment caused Ellis to turn back to his philosophical roots of Greek, Roman, and ancient Asian philosophers and seek a more effective form of therapy. Ellis worked through many of his own problems by revisiting and studying the philosophies of Epictetus, Marcus Aurelius, Baruch (or Benedictus) Spinoza, and Bertrand Russell, and he began to teach his clients these principles.

By the mid-1950s Ellis had completely abandoned psychoanalysis and begun focusing on altering behavior by confronting clients on what he termed their *irrational beliefs*, and then teaching and strengthening their rational beliefs. In 1957, Ellis published his first book on *rational-emotive therapy* (RET), *How to Live With a Neurotic*. Two years after this publication, Ellis founded the Institute for Rational-Emotive Therapy and conducted workshops on RET principles for other therapists. Ellis continued to revise and expand on his style of cognitive-behavioral therapy. In the early 1990s the institute, which is now called the Albert Ellis Institute, sponsored a conference titled “A Meeting of the Minds. Psychoanalysis and cognitive-behavior therapy: Is integration possible?” that resulted in changing the name of the therapy from rational-emotive therapy (RET) to rational emotive behavior therapy (REBT). Albert Ellis published more than 50 books and over 600 articles on REBT, sex,

and marriage. REBT has become a staple in cognitive therapy.

---

## EVIDENCE-BASED TREATMENTS

---

Within the past 15 years, the field of psychotherapy has wrestled with how to identify the type and nature of evidence that will allow one to validly determine if and when a treatment is likely to be helpful or harmful. Numerous factors, including concerns expressed both by individual citizens and their political representatives, the diverse and contradictory nature of many claims about psychotherapy efficacy and effectiveness, and the alarming number of instances of damage produced by psychotherapy as reported in the news media, fueled these discussions. The debate over how to define an “effective treatment” in the fields of counseling and mental health has revealed some significant schisms among those who adhere to different methods of researching and practicing psychotherapy and counseling.

While counseling and clinical psychology have always been concerned with identifying the effectiveness of psychotherapy, the topic rose to a visible level

when the Society of Clinical Psychology (Division 12 of the American Psychological Association, or APA) initiated a task force to identify treatments for which research evidence on treatment efficacy was available. This task force was initiated in 1993 and issued its first report of *empirically validated treatments* (EVTs) in 1995, with subsequent reports being presented in 1996 and 1998. Each report contained a list of brand-name treatments that were judged to meet certain criteria of effectiveness for a particular diagnostic group. However, as the list of effective treatments grew with each report, so did the concern both with what treatments were still missing from the list and with how “effectiveness” was judged for those treatments that were listed.

Eventually, more than 150 different models and manuals of treatment were identified by different working groups and professional associations, as being “empirically supported.” Armed with the list of endorsed procedures, clinicians faced a daunting task in their search to provide help to the struggling consumer or to achieve demonstrable levels of competence in order to service those who sought their help.

To address criticisms that the original task force report was too restrictive and exclusionary, the initial term of *empirically validated treatments* was changed in 1998 to *empirically supported treatments* (ESTs). This term was thought to be less strident and narrow. Likewise, the criterion of empirical support was expanded from two independent controlled trial comparisons to a requirement that a treatment’s value also should be supported by a preponderance of available scientific evidence. Unfortunately, these modifications did not address the types of concerns that were emerging with the Division 12 effort.

Increasingly, individuals raised concerns that the list of brand-named therapies favored narrow theories over important factors within the relationship and the participants (therapist and client). They argued that these extratherapy factors contributed to change at least as much as did the treatment model itself. Many scholars pointed out that head-to-head comparisons usually found that there were negligible differences among various treatments in the actual amount of change accounted for and that treatments, at best, accounted for only about 10% of the change that was observed in patients over the course of treatment. The scholars and practitioners who raised these concerns asserted the importance of a new way of assessing the nature of effective treatments, one based on an analysis of

research on participant and interpersonal contributors to the therapeutic relationship itself.

### Empirically Supported Relationships

Concerned with the way ESTs were being identified, Division 29 (Psychotherapy) of APA initiated a task force to look for a complementing alternative that would be more compatible with views regarding the importance of the therapeutic relationship. This task force focused on defining what came to be called *empirically supported relationships*, or ESRs. The identified empirically supported relationship factors included participant qualities and treatment processes that were conducive to change, but that were not part of most formal models of psychotherapy. The task force members reviewed available literature and constructed a list of variables and qualities that were either “probably” or “possibly” associated with beneficial outcomes. The most promising of these qualities included the therapeutic alliance, empathy, patient resistance, level of functional impairment, goal consensus and collaboration, group cohesion, positive regard, genuineness, and management of countertransference. Efforts to parse these various factors on the basis of their importance concluded that patient variables (i.e., severity of distress, functional impairment, etc.) account for approximately 25% to 30% of the total outcome variance, the therapy relationship or alliance accounts for a further 10%, the person of the therapist accounts for 8% of total change, and the specific treatment methods employed may add as much as another 8% to the successful prediction of outcomes. While slightly different percentages than these have been suggested by other scholars, using different statistical procedures, the therapeutic alliance is generally accepted as being quite salient as a predictor of change.

These findings did not end the disagreements among proponents of EST and ESR perspectives. Each perspective has been criticized for being too narrowly focused and failing to integrate all or most of the important constructs that have been indicative of benefit. They each have also been criticized for being too wedded to certain research methodologies at the exclusion of other, equally respected ones. Efforts to fashion common ground among these various perspectives have taken one of two directions. They have sought either to expand the nature of the evidence on which “validity” is to be judged, in order to be more

inclusive of different methodologies and preferred variables (e.g., the APA 2005 Presidential Task Force on Evidence-Based Practice), or to establish a set of guiding principles that can incorporate and integrate concepts from both EST and ESR perspectives (e.g., The Division 12/North American Society for Psychotherapy Research Task Force on Principles of Effective Change).

### ***The APA 2005 Presidential Task Force on Evidence-Based Practice***

The president of APA in 2005 initiated a task force on evidence-based practice as part of his presidential initiative. The task force was charged with addressing three specific issues:

1. How to incorporate the wide range of empirical evidence into the application of psychology
2. How to incorporate the roles of scientific findings and clinical expertise in decision making, including the process by which practitioners must choose among and incorporate available research
3. How to highlight the relative importance of different patient variables in treatment of decision making

After much deliberation and input from multiple groups, the task force concluded with a call to extend the definition of what constitutes “empirical support” to include therapist experience and judgment as well as patient preferences and values. The final report of the task force defines *evidence-based practice of psychology* (EBPP) as a practice that seeks to incorporate current, empirical, research with clinical expertise in regards to a patient’s individual characteristics, cultural background, and personal preferences for psychotherapy. The new EBPP was distinguished from the old, empirically supported treatments by its encouragement of clinicians to use subjective judgment and personal opinions, along with patients’ expressed preferences and values, whenever available research findings seem to be inadequate to the task of psychotherapy. By this means, the EBPP task force attempted to integrate the treatment method and procedures with a more global process of assessment, case formulation, and the power of the therapeutic relationship.

To accomplish the broad purposes of their mission, the APA’s presidential task force gave special consideration to the roles of three broad classes of

variables—research, clinical expertise, and patient variables. Integrating these concepts, they concluded that

1. It is not sufficient to know that a given treatment works. Clinicians must use their own experience and judgment to determine the applicability, feasibility, and usefulness of the intervention in the local or specific setting where it is to be offered.
2. Practitioners should consider nontreatment factors that affect treatment outcome, such as the individual therapist, the relationship, and the patient. Good therapists should be able competently to incorporate these different sources of evidence into treatment of decision making.
3. Clinical expertise is necessary in order to incorporate available research with the characteristics of a particular patient. They defined *clinical expertise* as the experience and knowledge attained by psychologists through education and training that ultimately results in effective therapeutic practices.
4. The influence of patient qualities and characteristics should be incorporated into the treatment program and integrated with treatment through the medium of therapist experience and judgment.

### ***The Joint Task Force on Empirically Supported Principles of Therapeutic Change***

Two fundamental concerns with the conclusions by the APA's 2005 presidential task force bolstered the development and foundation of a second task force. The former conclusions were seen as (a) placing unfounded faith in unproven and demonstrably fallible clinical judgment and (b) urging the integration of patient, therapist, relationship, and treatment factors without providing any useful guidance for how this might be accomplished. A task force representing, jointly, the Society for Clinical Psychology (Division 12 of APA) and the North American Society for Psychotherapy Research (NASPR) was convened when members and officers within these groups came to believe that neither EST nor ESR, nor APA's 2005 presidential task force, offered a clear rationale for how patient, therapist, treatment, and relationship variables were to be balanced and integrated.

The joint task force argued that the emerging EST, ESR, and EBPP perspectives failed to capture the

importance of integrating multiple dimensions and processes. Because each of these task forces and working groups emphasized only one set of variables (treatment models, relationship factors, or participant factors) at the relative expense of the others, it was thought that they were poorly positioned for integrating these various domains of influence. Moreover, it was feared that APA's presidential task force, by making clinician judgment the final arbiter of "effectiveness," ignored the fallibility of human judgment, the role of emotion in distorting perspectives, and the self-serving nature of professional judgment for which science had been developed. A more objective and integrative method offering delineated directions for applying concepts from the patient, the therapist, the relationship, and the treatment was needed.

The Joint Task Force on Empirically Supported Principles of Therapeutic Change sought the answers to two cardinal questions:

1. What is known about the nature of the therapy participants, relationships, and procedures within treatment that induces positive effects across theoretical models?
2. How do factors related to these domains work together to enhance change?

The specific mission of the joint task force included an attempt to distill the influences of participant, relationship, and treatment factors into a set of cross-cutting, empirically supported, and informed principles that were not tied to any one theory or perspective of psychotherapy. Unlike APA's 2005 presidential task force, the evidentiary bases for the principles were to be founded directly on scientific evidence. To resolve some of the differences between the EST and ESR models, moreover, this task force accepted a broad view of acceptable research methodologies, as long as the methods research was published in credible scientific journals, based on peer review.

Ultimately, 24 senior scholars and 21 associated scholars were chosen to work on the principles task force. These authors were divided into groups, each addressing one domain of the variables (participant factors, relationship factors, treatment methods) and one type of problem for which counseling and psychotherapy may be useful (depression, anxiety, personality disorder, or chemical use disorders). These groups were asked to extract from the previous task

force reports, and other major research volumes, all of those treatment outcome studies that represented the particular mix of variable domain and problem area to which they were assigned. They were then to dissect the relevant studies, summarize and tabulate the results, and articulate a set of guiding principles that were supported by a preponderance of the available research and that could inform the therapist in treating patients with a particular problem.

The joint task force compiled a set of 61 principles that served to identify aspects of patients, therapists, relationships, and treatments that contributed in predictable and empirically reliable ways to outcome. Twenty-six of these principles were similar in two or more of the four diagnostic problem areas reviewed. The similarity of these principles across problem areas resulted in their being designated “common” principles. In contrast, 35 of the principles were only identified as being adequately supported in one of the four problem areas and thereby, earned the designation as being “unique” principles.

Twenty-eight of the principles (5 common and 23 unique) described ways that extratherapy qualities of the therapist and patient facilitated change in the successful treatment of various problems. The principles emphasized the value of flexibility, the ability to tolerate ambiguity, and tolerance for one’s own negative responses to others. They also identified prognostic indicators among patients, such as the negative affect observed in those with personality disorder, those who lack adequate social support, those with severe problems, and those with a chaotic history and background.

Eleven of the derived principles addressed the use and value of the therapeutic relationship in facilitating change. Most of these (9 of 11) were common to two or more of the problem areas. These latter principles generally pertained to the use of a collaborative framework and to the therapeutic skill required to develop and maintain the therapeutic alliance.

Twenty-two research-informed principles reflected the effective use of different classes of interventions, each being grouped by the impact it had on psychotherapy process (e.g., directive vs. nondirective, insight vs. symptom change). These principles were almost equally divided among those that were common across different problems (12 of 22) and those that were unique to the type of problem being addressed. These principles were clearly integrative, and many of them described ways to tailor interventions

to fit different qualities of the patient and the context in which he or she lives.

## Future Directions

The balancing and integration of science and practice in counseling psychology continues to be a work in progress. The hopeful observation is that there is a continuing dialogue among the various stakeholders in this debate and the discourse is likely to be productive.

## EXPECTATIONS ABOUT THERAPY

---

Client expectations about counseling and psychotherapy are widely believed to influence the therapy process and outcome. Theorists from disparate theoretical persuasions have included expectations as a central construct in their theories. Research on the common factors that account for much of the success of psychotherapy confirms the influence of client expectations.

### The Construct of Expectations

#### *Development of Construct of Expectations*

Oswald Kulpe and Edward B. Titchener formulated the concept of an expectation as a cognitively mediated preparatory set or disposition to behave in a particular manner in a given situation. Narziss Ach named this disposition a “determining tendency,” thereby emphasizing the effects of expectations on perception and behavior. By definition, therefore, expectations influence perceptual and judgmental processes, learning, and behavior.

Jerome Bruner, Leo J. Postman, and Harry Helson elaborated the role of expectations in influencing behavior. Bruner and Postman theorized that the process of perception begins with an expectation or hypothesis. Helson viewed expectations as critical determinants of people’s “adaptation level” (i.e., the cognitive norms people use in interpreting sensory information). Learning theorists such as Edward C. Tolman (cognitive theory), Clark L. Hull and Kenneth Spence (drive reduction theory), and Julian B. Rotter (social learning theory) viewed learning as a function of the reinforcement of one’s expectancies regarding the outcome of behavior in a given situation.

Social psychologists incorporated expectancies as a central construct in explaining social cognition. Cognitive *expectancies* (i.e., preparatory sets) are viewed as primary determinants of behavior in George A. Kelly’s personal construct theory, Kurt Lewin’s aspiration theory, Leon Festinger’s cognitive dissonance theory, and Theodore Newcomb’s attraction theory.

#### *Expectations in Counseling and Psychotherapy*

Theorists also viewed expectations as central to the success of psychotherapy. Clients’ expectations

influence their decision to enter into and remain in therapy and they moderate the effectiveness of therapy. Clients approach therapy with expectancies regarding the nature of therapy and the roles they and their counselors will assume. Counselors’ and clients’ expectations are important determinants of their behavior in counseling.

Arnold P. Goldstein distinguished between prognostic expectations (e.g., beliefs concerning the probability of success in counseling) and participant role expectations (i.e., beliefs regarding the behaviors that will be displayed by the client and counselor). Bernard Apfelbaum suggested that clients expect one of three basic types of counselors. The *critic* is a cold, rigid, judgmental therapist who gives advice, but is not concerned with whether the client uses it. The *model* is a tolerant, accepting, permissive therapist. The *nurturant therapist* is giving, guiding, and protective. Expectations such as these influence people’s choice of a help giver, their perceptions of their therapists, the quality of the communication process, their persistence in counseling, and the effectiveness of counseling. Most of these theoretical assertions have been supported by empirical research.

### Early Research on Expectations About Therapy

Most research on expectations about counseling prior to the early 1970s focused on the placebo effect of expectancies and expectations regarding the therapists’ behavior.

#### *Placebo Effect of Expectancies*

The *placebo effect* was named after the practice in medical research of prescribing a benign treatment (e.g., a “sugar pill”) to a control group of patients. This allows researchers to determine whether spontaneous, non-treatment-related improvements occurred during the study. It is possible that the mere act of entering therapeutic treatment could stimulate improvement. Some psychologists theorized that all of the gain from therapy was the result of a placebo effect.

Research through the early 1970s investigated whether the gains observed in therapy were attributable to the mere expectation that therapy would be effective. Several early studies supported that theory. Wallace Wilkin’s critical analysis in 1973, however, demonstrated that those studies supporting the placebo

effect theory had not used suitable experimental controls. Studies in which effective experimental controls were used did not support the placebo effect.

Psychologists now understand that the creation of an expectation to benefit from therapy is one of the common factors associated with a positive therapeutic outcome. All approaches to psychotherapy strive to create hope and a more positive outlook on life by stimulating an expectancy to benefit from therapy. While advocates of the placebo hypothesis thought that expectancy effects accounted for all of the gain from therapy, psychologists now estimate that 15% of the gain from therapy is due to expectancy effects.

### **Therapist Behavior**

Another line of research investigated the types of behaviors students expected from counselors. In general, students expected their counselors to maintain confidentiality and to be thoroughly prepared for the interview, at ease with them, and skilled at dealing with their problems. Consistent gender differences in expectancies were observed. Males expected a more directive, critical, and analytical counselor; females expected a more nonjudgmental, permissive listener. However, both men and women preferred that the therapist offer advice.

### **Measuring Expectations**

Prior to the 1980s, investigators constructed their own questionnaires to measure expectations about counseling. This resulted in numerous problems. Each study focused on a single or very limited range of expectancies and often a single item was used to measure expectancies. The single-item and multiple-item scales that were used lacked reliability and validity. Many of the instruments did not distinguish clearly and accurately between expectations, preferences, and perceptions, and many instruments defined expectations inaccurately. Systematic programs of research were lacking. These practices yielded idiosyncratic findings and interfered with the development of a coherent understanding of expectancy effects.

### **Expectations, Preferences, and Perceptions**

Distinguishing among expectations, preferences, and perceptions is critically important because research reveals differences among them. Expectations are subjectively held probability statements that

represent the person's estimate of the likelihood that an event will occur (e.g., the counselor will understand my problem) or a condition will exist (e.g., the therapist will seem trustworthy). Expectations refer to the future, and they can exist in the absence of direct experience with the event or condition. Some investigators have used *anticipations* as a synonym for *expectations*, but that term is most commonly used in studies of serial anticipation learning. *Expectations* is the term that is more commonly used throughout psychology, and particularly in studies examining issues pertaining to counseling and psychotherapy.

*Preferences* refer to the strength of the person's desire that an event will occur or a condition will exist. Preferences can be stated in the absence of direct experience with the event or condition. Some investigators have used *hope* as a synonym for *preference*, but hope (i.e., to look forward with desire and reasonable confidence) involves both expectations and preferences. Knowledgeable psychologists avoid the use of *hope* in studies of expectations and preferences.

*Perceptions* refer to the person's comprehension, understanding, or knowledge of an event or the existence of a condition gained by means of direct observation. A perception is a subjective statement of fact. Perceptions refer to events or conditions that occurred in the past or that are ongoing at the present. Perceptions require direct experience with the event or condition.

### **Expectations About Counseling—Brief Form**

The development of the Expectations About Counseling—Brief Form (EAC-B) was an important landmark in psychologists' efforts to investigate the influence of expectations on the counseling process and outcome. The development of a reliable and valid measure of expectations and the clarification of the constructs of expectations, preferences, and perceptions helped to advance the methodological rigor of research on expectations about counseling.

The EAC-B is a 66-item instrument that measures 17 specific expectations and 3 broader expectations factors. The 17 expectations are grouped into five clusters, expectations about: client attitudes and behaviors (Responsibility, Openness, and Motivation), counselor attitudes and behaviors (Acceptance, Confrontation, Genuineness, Directiveness, Empathy, Self-Disclosure, and Nurturance), counselor characteristics (Attractiveness, Expertise, Trustworthiness, and Tolerance), characteristics of the therapy process (Immediacy and

Concreteness), and quality of outcome (Outcome). The three factors measured by the EAC-B are the expectation to make a Personal Commitment, the expectation that the Facilitative Conditions will be present during therapy, and the expectation of Counselor Expertise. Analysis of counseling research in the 1990s revealed that the EAC-B was the sixth most commonly used instrument in published counseling psychology research. The instrument has been translated into Chinese, Dutch, French, Icelandic, Polish, and Spanish and used around the world.

### ***Reliability and Validity of EAC-B***

Numerous studies have documented the internal consistency, test-retest, and parallel forms reliability of the EAC-B and its validity using varied criteria. The factorial validity of the EAC-B has been demonstrated across variations in culture, language, and client or nonclient status. The three-factor structure has emerged from analyses using all of the major variations of the components analysis and factor analysis procedures. The evidence demonstrates unequivocally that the factor structure of the EAC-B is not an artifact of the item format, and that the EAC-B measures constructs that are distinctly independent of related constructs such as career concerns, counseling readiness, ego strength, level of psychosocial development, perceived psychological difficulty, perceptions of counseling, perceptions of counselors, and personality.

Much of the research on expectations has been performed on college and university campuses using typical students. Psychologists have questioned the generalizability of research on students to clients seeking services in university or nonuniversity settings. There is encouraging evidence that the results obtained with nonclient students are generalizable to student and adult clients. Studies comparing students (not in counseling) to student and nonstudent clients indicated that the expectations of the students did not differ from those of either of the client groups, and that the internal structure of the EAC-B was the same for students and adults who were seeking counseling.

### **Importance of Expectations**

The likelihood of mental illness is higher in the 15- to 24-year-old age range than in other age ranges, and suicide is the third leading cause of death in that age range. Nevertheless, a national study by Darrel A. Regier and his associates of more than 20,000

individuals revealed that only 28.5% of those who met the criteria for a mental or addictive disorder received any treatment during that year. Many psychologists believe that negative opinions about mental illness and expectations about psychotherapy are responsible for the underuse of mental health services.

### ***Prevalence of Unrealistic Expectations***

A national survey of practicing therapists conducted in 1993 by Howard E. A. Tinsley revealed that a significant proportion of their clients have unrealistic expectations about counseling. The percentage of therapists reporting that “some, many, or most” of their clients have unrealistically low expectations ranged from 7% for the expectation of counselor expertise to a high of 81% for the expectation to assume responsibility for the success of therapy. The percentage of therapists reporting that “some, many, or most” of their clients have unrealistically high expectations ranged from 19% for the expectation of client openness to a high of 88% for the expectation of counselor directiveness. Adding the percentage of clients that have unrealistically low and high expectations (e.g., 67% + 19% = 86% for client openness) reveals that a sizable majority of clients have unrealistic expectations of counseling. In general, clients tend to underestimate the work they will have to do in counseling and to overestimate the skill of the counselor, a phenomenon that has been described as “magical thinking.”

### ***Consequences of Unrealistic Expectations***

The national survey conducted by Howard E. A. Tinsley and associates revealed that from 36% to 100% of therapists view unrealistically low expectations as detrimental to the counseling process, depending on the specific expectation. Unrealistically high expectations about counseling are viewed as detrimental by 38% to 93% of therapists. Thus, experienced therapists report that a majority of their clients have unrealistic expectations about counseling and that those expectations are detrimental to the therapeutic process.

### **Expectancy Manipulation**

One of the early goals in therapy is to help the client form more realistic expectations about the therapy process, but therapists describe that as difficult to accomplish. The percentage of therapists who view the modification of unrealistic expectations as

moderately difficult ranges from a low of 59% for Facilitative Conditions to a high of 66% for Personal Commitment and Counselor Expertise. Therapists most frequently report that three aspects of Personal Commitment (Attractiveness, Outcome, and Responsibility) and two of the Facilitative Conditions (Nurturance and Trustworthiness) are very difficult to modify.

### **Overview of Expectancy Manipulation Research**

Close to 50 studies have investigated the effectiveness of alternative approaches to modifying expectancies. The individuals studied in this research have included children, counseling center clients, college students, church group members, community mental health center clients, psychiatric outpatients, schizophrenic patients, rehabilitation center clients, and veterans receiving vocational counseling. Investigators have attempted to modify expectancies for the facilitative conditions (e.g., counselor expertness, attractiveness, and trustworthiness), prognosis for therapy, therapist techniques, therapist theoretical orientation, client behaviors and role expectations, and general counseling process and procedures.

In aggregate, these studies investigated six types of interventions. Audiotaped expectancy manipulations generally present research participants with an introduction to therapy in the form of direct instruction or examples of effective and ineffective interviews. Videotaped or motion picture interventions typically provide didactic information for role induction purposes. Verbal instructions usually involve telling participants face-to-face about the nature of therapy, appropriate in-session behavior, and prognostic expectancies. Printed materials typically provide information about the expectancies the investigator is attempting to change. Use of the counseling interview to modify expectancies typically involves administration of an expectancy measure, conducting an intake or initial interview, and then readministering the same expectancy measure. The single study in which a complex intervention was used involved a preparatory psychotherapy class in which written and verbal materials, a film, a group discussion and role-playing exercises were used.

Methodological weaknesses are widespread in this research because investigators violated basic principles of experimental design. They failed to randomly assign participants to the experimental conditions, so

any differences observed after the experimental intervention may be due to initial differences among the groups. Many used a pretest–posttest design in which participants' expectations were measured prior to the manipulation. This alerts participants to the issues under investigation. For example, asking participants whether they expect a therapist to use confrontation sensitizes them to this issue. Furthermore, most of the investigations focused on a single or narrow range of expectancies. Typically, the measures used in this research consisted of single items, lacked demonstrated reliability and validity, used invalid definition of expectations, and confused expectations, preferences, and perceptions. The investigators often failed to evaluate the long-term effects of the expectancy manipulations, to relate expectancy manipulation to any important aspect of the therapeutic process or outcome, or to perform a manipulation check (i.e., to determine whether the manipulation had the desired effect). Finally, when multiple manipulations were performed, they failed to examine the possibility of interactions among the manipulation procedures.

### **Effectiveness of Modification Strategies**

Despite these flaws, three conclusions can be drawn from the literature. First, the use of complicated experimental interventions is unnecessary and unsuccessful. Audiotaped and videotaped interventions are most likely to be successful. Printed materials typically have been ineffective and the effectiveness of verbal interventions is doubtful. Second, there is no evidence that actual experience in counseling is an effective method of changing expectations; the studies that examined this approach were of quite poor quality. This procedure is more costly than a direct experimental intervention and it is unlikely to be more effective. Third, the conditions under which the expectancy manipulation strategies are effective are unclear because each type of intervention frequently failed to produce significant results.

There are theoretical and empirical reasons for viewing expectancies as important to the success of counseling, there is unambiguous evidence that unrealistic expectancies are common and detrimental to the counseling process and outcome, and therapists report that changing expectations is difficult. These suggest that a concerted focus on the efficacy of expectancy manipulation strategies deserves a high priority from psychologists.

## Correlates of Expectations

### *Culture*

Expectations are learned and modified through interactions with the environment. This suggests that the social and cultural milieu in which people develop influences their expectations about counseling. However, three caveats suggest caution when interpreting the research on cross-cultural differences in expectations. First, most theories of counseling and psychotherapy reflect the North American and Western European (i.e., Euro-American) cultural perspectives. These theories define the desirable roles and behaviors of the therapist and client, and consequently the interpretation of research comparing the expectations of persons from different cultural heritages. Second, the rate of cross-cultural interaction is increasing exponentially. The cultural heritage of each generation is different from that of the preceding generation, so research findings obtained only a couple of decades ago may already be dated. Finally, while this issue has enjoyed some research attention, the body of evidence is so sparse that only a very tentative summary can be offered.

In general, Euro-Americans are more skeptical than others about the expertise of the counselor and the likelihood that facilitative conditions will be salient during therapy. They are more pessimistic that the counselor will be able to help them determine what is the matter with them, help them identify particular aspects of their behavior that are relevant to their problems, or help them solve their problems. They have lower expectations that the counselor will explain what is wrong and offer useful suggestions and advice. They think it is less likely that the counselor will understand and help them to better understand and explain their feelings. They also regarded it as less likely that the counselor will give them support, encouragement and reassurance, or praise them when they show improvement.

Individuals raised in Middle Eastern, Islamic, and African cultures are somewhat similar to each other in their expectations of counseling, and more similar to Euro-Americans and individuals raised in a Spanish culture than to Asians. When compared to persons raised in a Euro-American culture, they generally have stronger expectations regarding the likelihood of counselor expertise and facilitative counselor attitudes, behaviors, and techniques such as immediacy and concreteness. In other respects, their expectations differ little from those of Euro-Americans. Too high

an expectation of counselor expertise may represent a form of magical thinking, but the skepticism underlying low expectations for counselor expertise is not a healthy prognostic sign either. Counselors working with clients exhibiting either type of unrealistic expectation typically report that they need to help the client gain a more realistic expectation before progress in counseling is likely.

Asian individuals expect the counselor to remain more disengaged than persons from other cultures. They report stronger expectations that the counselor will be courteous, respect their privacy, and keep their relationship distant and smooth. In general, they expect to be more guarded in revealing important information to the counselor. They expect the counseling process to be less focused on their feelings and problematic behaviors, and they expect to be less personally revealing about those issues. Perhaps as a reflection of this expectation regarding personal revelation, they also have lower expectations that the counselor will genuinely reveal him- or herself.

Asian individuals expect to take less personal responsibility for making decisions, for talking about their concerns during counseling, and for working on their problems outside of counseling. They also have lower expectations to work during the counseling sessions on new behaviors and ways of solving problems. Relatively speaking, they expect the counselor to be less likely to focus on inconsistencies between their feelings and behaviors and between their goals and present behavior, and they are more pessimistic about gaining a better understanding of themselves and improving their relationships with others. Counselors who are not aware of multicultural differences may view the behavior of their Asian clients as indicating an unwillingness to work hard and make a serious commitment to therapy.

Persons from Hispanic cultures have a stronger expectation to take personal responsibility for the success of therapy than Asians (and in some respects stronger than all other groups). They have a stronger expectation to persist in counseling despite the occurrence of painful and unpleasant times. They expect to work on their concerns outside of counseling and to practice new behaviors and new ways of solving their problems during the counseling interviews. They have stronger expectations to take personal responsibility for making decisions during therapy, for gaining a better understanding of themselves and others, and for improving their relationships with others. They report

stronger expectancies to openly discuss their emotions and problems during counseling and to work with the counselor to better understand their feelings and discover aspects of their behavior that contribute to their problems. They expect to face up to inconsistencies in their thoughts and actions and inconsistencies between their goals and behaviors.

### **Developmental Level**

Erik Erikson theorized that life-span development progresses through a series of psychosocial stages characterized by developmental tasks. Completion of these tasks provides the individual with new methods of coping with the environment, new ways of viewing the world, and advancement to the next stage.

Expectations about counseling vary as a function of the development of mature educational plans, career plans, and lifestyle plans. The development of mature educational plans is associated with uniformly more positive expectations about counseling. The development of mature career and lifestyle plans is associated with a more varied pattern of change in expectations. Psychologists modify their counseling styles to communicate effectively with persons at different levels of psychosocial development.

Individuals' expectations about their own attitudes and behaviors during counseling are unrelated to their level of psychosocial development. However, their expectations of the counselor, the counseling process, and the outcome of therapy become more positive as they gain in psychosocial maturity. For example, expectations about the facilitative conditions become more favorable as psychosocial maturity increases. Developmentally less mature students are more skeptical that these conditions will exist, and they may be less likely to perceive the level of facilitative conditions that exist within the actual counseling relationship. Developmentally less mature students are also less likely to understand the necessity of working hard in counseling and of taking responsibility for the success of counseling. One early goal of therapists working with less developmentally mature students is to help them develop a sense of personal responsibility for the success of counseling.

### **Research Directions**

This entry highlighted numerous weaknesses in the research on expectations about counseling, including

the frequent use of instruments having no demonstrated reliability or validity and the lack of programmatic research. This entry also identified areas needing research attention. Perhaps the most significant oversight, however, is the lack of research on the effects of expectations about counseling on the counseling process, counseling outcome, and premature termination.

It is reasonable to think that clients' expectations will have an important effect on their behavior during therapy, at least during the first few sessions. The quality of the counseling relationship is critical to the success of counseling, regardless of the theoretical orientation and specific approach of the psychologist. Despite this, investigations of the counseling process have largely ignored client expectations.

One investigation of the relation of client's expectations to their level of involvement during career counseling hints of the importance of this issue. Clients having relatively high expectations of personal commitment and facilitative conditions were paired with clients having relatively low expectations on those factors. Both clients in a pair received services from the same therapist, and audiotapes of the first interview were rated to obtain measures of the client's level of involvement in therapy.

The clients with more positive expectations participated at a higher level of involvement during the initial interview. They were more willing to talk about themselves rather than people in general, more likely to become emotionally involved, and more likely to report personal reactions and to describe their feelings. In contrast, the clients who had relatively negative expectations of counseling talked about external events and limited themselves to descriptions of behaviors and intellectualized self-descriptions. They never departed from this guardedness during the initial interview.

These findings only hint at the importance of this line of research. Numerous studies have found that a high level of involvement is positively related to counseling outcome. Research that examines the relation of expectations to aspects of the counseling process and outcome has great potential to significantly advance knowledge of the therapy process.

## FACILITATIVE CONDITIONS

---

Facilitative conditions are those conditions or counselor attitudes that enhance the therapeutic relationship and are conducive to successful outcomes in counseling and psychotherapy. The three primary facilitative conditions were first suggested by Carl R. Rogers in his 1951 publication on the *person-centered* counseling approach. These conditions are *unconditional positive regard*, *genuineness*, and *empathy*. According to Rogers, if counselors express these core conditions, those being helped will become less defensive and more open to themselves and their world, and will tend to behave in more prosocial and constructive ways. Rogers believed that these three conditions were both necessary and sufficient for positive outcomes in the counseling process. Other theorists have argued that although these conditions may be necessary, they are not sufficient for positive therapeutic outcomes. Current discussions of common factors related to positive therapeutic outcome identify the *therapeutic relationship* as essential to client progress. The facilitative conditions are key to the establishment of a positive therapeutic relationship.

### Unconditional Positive Regard

Unconditional positive regard is the therapist's unqualified attitude of acceptance and a nonpossessive caring toward the client and toward the client's feelings and experiences. This involves a valuing of the client as a worthy human being regardless of his or her past choices, problems, or issues and a warm acceptance of

each aspect of the client's present experience as it unfolds in the here-and-now of the counseling context. The client's thoughts, feelings, and behaviors are not evaluated by the counselor as good or bad. This facilitative condition, in which clients are unconditionally accepted, provides clients with a therapeutic context in which they are given the freedom to be themselves and experience their own being, thoughts, and feelings without any outside conditions or demands. This freedom gives the clients a safe, accepting context in which to express and explore the many deeper hidden dimensions of themselves and the freedom to self-reflect and consider new choices and options.

Having unconditional positive regard for the client does not mean condoning all the client's actions. For example, a counselor working with a mass murderer would have unconditional positive regard for the client. The counselor would have an acceptance of the anger the client is expressing at being charged with murder. The counselor does not necessarily agree with the client's choice to have committed murder, but does have unconditional positive regard for the client as a person and the client's experience of the emotion of anger. The counselor accepts the client as a fellow human and values the client as such, regardless of the client's choices. A second example is a counselor working with a person who has issues surrounding addiction. The counselor would have unconditional positive regard for the client and his or her experience of addiction. The counselor's liking the client would not be conditionally based on the client's stopping use of drugs or alcohol. The counselor would value the client as another person. However, Rogers understood that not all counselors could have unconditional

positive regard for all clients. In these instances, referral to another counselor is the best option.

### Genuineness

Genuineness, which has also been called *congruence*, *realness*, and *transparency*, is the state or condition in which the counselors are themselves in the context of the counseling relationship. Rather than adopting the role of expert or a facade of detached objectivity, the counselors openly and honestly express themselves as “real” and “transparent” people to the client. In this congruent state, the counselors are aware of their own feelings and reactions to what is happening in the present (here-and-now), aware of their attitudes toward the client, and able to honestly express their awareness to the client, as appropriate.

There is a close match or congruence between the internal experience of the counselor and what is outwardly expressed to the client. The facilitative condition of genuineness enhances the sense of realness, immediacy, and openness in the therapeutic relationship and creates a context of safety and sharing. It diminishes the sense of professional distance between the counselor and client. The counselor’s self-awareness, honesty, and openness about moment-to-moment feelings and attitudes provide a model for the client’s own therapeutic work and life. In the case of a client discussing the death of a parent with little or no emotion, an example of counselor genuineness would be the counselors saying to the client, “I’m feeling a great sense of sadness about the death of your father.” At this point, most clients would then respond in some way regarding the father’s death and their previously unexpressed sadness. In the case of a client who expresses a desire to attend college yet continually takes actions that sabotage this goal—even after promising the counselor to change some of the sabotaging behaviors—the counselor might say, “I am feeling frustrated with how you say you want to go to college on the one hand, and on the other you make some choices that damage your chances of going to college. I wonder if on some level you’re not sure you want to go to college.”

### Empathy

Empathy or empathic understanding involves a deep, accurate awareness of the client’s emotional and cognitive world. It is the ability of the counselor to see

deeply into the subjective experience of the client and to sense the client’s private world. Empathy is an active and ongoing understanding and reflection of feeling and meaning that occurs in the here and now of the therapeutic session. This includes the ability of the counselor to sense the clients’ moment-to-moment feelings and understand the clients’ worldviews, structures of meaning, and interpretations of events. Furthermore, the counselor is able to effectively and accurately communicate this understanding to the clients in a way that clarifies the clients’ comprehension of their own experiences. The facilitative condition of empathy allows clients to feel understood, acknowledged, and accepted in a way that can greatly enhance the therapeutic relationship and allow for a deepening of therapeutic insight. Advanced empathy is a state where the counselor is so deeply aware of the client’s world and emotions that the counselor is aware of things that the client has yet to become aware of in that world. For example, in the case of a person going through divorce, the client may be angry with his spouse. The empathic counselor acknowledges the client’s obvious anger at his wife, but with advanced empathy senses the client’s underlying anger at himself for how he contributed to the breakup of the marriage.

## FALSE MEMORIES

---

False memory refers to the phenomenon of “remembering” something that never actually occurred. False memories can be small, such as mistaken details of an event, or they can consist of whole events that never actually happened. People experiencing a false memory generally believe the memory to be true, and often experience sensory detail and emotions, just like with real memories.

### How Memory Works

#### *Not All Memories Are Created Equal*

Memory is not perfect. It does not record like a tape recorder or video camera. Instead, people tend to store bits of information from their experiences. These portions of memory are susceptible to distortion because memory is a reconstructive process. People tend to create memories from the various bits of stored information in their brain each time they remember something. In the process, details are sometimes changed or chunks of new material added.

Another reason for imperfect memory is that people tend to store the gist of events in their memories instead of the details. Not all events that people experience end up being stored as long-term memories. Many aspects of daily life go unnoticed or are quickly forgotten. For example, people fail miserably when asked to describe a U.S. penny because details, such as the way Abraham Lincoln is facing and the location of the date on the penny, simply aren't important enough to be remembered.

Time is also important to people's ability to recall information. Memories fade as time passes and become more prone to distortion. Also, the phenomenon of *infantile amnesia* makes it difficult for people to remember events from when they were very young.

Adults generally cannot remember events that occurred before age 2, even if the events were very important or traumatic.

### *Distortion in Memory*

How does memory distortion occur? One important influence on memory is called a *schema*. Schemas are ways of organizing knowledge into predictable patterns or expectations. For example, people have schemas about how certain types of people are expected to behave (stereotypes) and about how events are supposed to happen (such as how to behave in a restaurant). By providing a “script” for how events are supposed to unfold, schemas act as energy savers that allow the mind to take shortcuts when processing information.

Usually these shortcuts work well, but sometimes they mislead memory. For example, when people are presented with a list of words that include *bed*, *rest*, and *dream*, but not the word *sleep*, and they are asked to recall all the presented words, people often falsely report the word *sleep* as being part of the list. This occurs because the list of words forms a script that is highly consistent with sleep. Because people's memories are influenced by schemas, they sometimes “remember” things that are consistent with the script for an event, even though those events did not occur.

False memories also occur when people make mistakes about the source of certain information. For instance, someone could mistakenly recall an event happening to him or her when in reality the person merely dreamed or imagined it. *Source monitoring errors* occur when information is recalled correctly, but the source is not.

Psychologists previously believed that certain highly emotional memories of great personal importance—*flashbulb memories*—were impervious to distortion or forgetting. However, even these memories are prone to distortion. In one psychological investigation, people were asked the day after the *Challenger* explosion in 1986 to write an account of how they had first learned about the event. Three years later, these same people were asked to describe again how they had learned about the tragedy. A surprising amount of memory distortion was present in these recollections, even for those people who reported intense emotional reactions to the event. In fact, 25% of the participants had completely false memories of learning about the explosion. No one

recalled the incident without some distortion of facts, and only 7% recalled the episode with close to perfect accuracy. When shown their earlier written accounts, those individuals with false memories expressed surprise at the discrepancies and remained unable to remember the true details of the event.

### **How to Create False Memories**

False memories for events can occur naturally, as in the *Challenger* study, or they can be created through the actions of another person. One way that false memories can be created is through a phenomenon called the *misinformation effect*. This occurs when a person is given misleading information about an event which they subsequently incorporate into memory. In one experiment, participants watched a slide show of a car accident involving either a stop sign or a yield sign. They were then asked questions containing information about the sign that was either consistent or inconsistent with what they had actually seen (for example, “Did another car pass the red Datsun when it was parked at the stop sign?”). When shown two slides of the accident and asked to choose which they had seen, 75% of those who had been asked questions containing consistent information about the sign chose the correct slide. After misleading questions, they were correct only 41% of the time. Since they could have guessed correctly 50% of the time, this indicates the strong influence misinformation can have on memory.

Suggestive and leading questions can also distort memory reports. A question like “How fast were the cars going when they smashed into each other?” can lead accident witnesses to recall a higher speed than the same question asked with *hit* substituted for *smashed into*. Multiple leading questions can be particularly dangerous.

Although these methods are used by researchers to deliberately create memory distortion in participants, similar influences exist in the real world. For example, one witness may inadvertently give another witness incorrect information about a crime. The second witness may then come to mistakenly remember this information as being true. Also, research and recent cases of wrongful conviction have shown that suspects can be led to falsely confess to crimes they did not commit when subjected to certain interrogation practices. Police routinely provide misinformation to suspects during interrogation, which in some rare

cases may cause the suspect to create false memories of committing a crime.

## **False Memories in Clinical Settings**

### **Therapeutic Techniques**

Some practices in clinical settings may enhance the likelihood of developing false memories. Attempts to recall “repressed” memories can be particularly dangerous. *Repressed memories* refer to memories that a person has suppressed out of conscious awareness, but that are thought to exist still whole and unchanged deep in the mind. There is little empirical support for the notion of repressed memories. Instead, research demonstrates that techniques used to aid recall of memory can create false memories. Techniques that encourage the client to imagine how events might have occurred, or rely on dream interpretation, are particularly prone to source-monitoring errors. Hypnosis and the use of “truth serum” drugs, such as sodium amytal, also place clients in suggestive states in which they are susceptible to memory distortion.

### **Legal Implications**

False memories can have harmful consequences for patients, family members, and clinicians. Delayed discovery laws in some states allow a person with “recovered” memories of abuse to bring charges against his or her alleged abuser years after the normal statute of limitations has ended. If these memories are false, these legal proceedings can result in lawsuits or criminal convictions against an innocent person. Clients who recover memories in therapy and later reject those memories as false sometimes sue the therapist for malpractice. In the case of *Burgis v. Braun* (1997), a woman and her two children developed memories of belonging to a satanic cult, where among other things they were forced to eat thousands of babies. No evidence ever arose to support these outlandish claims. Eventually, the family sued, and was awarded a \$10 million settlement.

### **Avoiding False Memories**

Serious false memories of the kind described above are rare, and reputable clinicians take steps to reduce their occurrence. They avoid suggestive questions and therapeutic techniques, in favor of open-ended and

balanced discussions and activities. Warning people of the possibility of false memories and asking them to focus on the source of information has been shown to reduce the rate of memory distortion. One way to minimize the likelihood of false memories is to be aware that they exist, and to understand what factors aid memory accuracy and what may make memory susceptible to distortion.

---

## FORGIVENESS

---

Forgiveness occurs in an interpersonal context, as a response to the intentional harm caused by another.

When one individual insults another, reveals confidential or embarrassing knowledge, harms another or another's valued property, or is unfaithful to a committed partner, then the victim rightly feels that a moral transgression has occurred. One may seek justice to repair the harm or not, but the immediate cognitive, emotional, and behavioral responses are likely to be condemnatory, angry, and retaliatory. The long-term effects of the harm may involve angry rumination, chronic negative feelings, and obsessive thoughts of revenge. These long-term effects may lead individuals to seek alternative coping responses, either on their own or with therapeutic intervention. Forgiveness represents an alternative response that leads to more positive thoughts, feelings, and actions, while reducing anger, anxiety, and depression.

### The Definition of Forgiveness

Forgiveness is often defined by exclusion. Forgiveness does not involve condoning an offender's behavior, nor does it imply that the offense is forgotten. One may seek to understand the offender and the reasons behind his or her behavior in order to achieve some cognitive resolution. To the extent that the behavior can be excused, due to inexperience or extenuating circumstances, then forgiveness is not relevant. Finally, forgiveness does not necessarily imply reconciliation.

There is no consensually agreed-upon definition of forgiveness, but there is some common ground for forming an understanding of the concept. Forgiveness is an intrapersonal phenomenon, occurring within the individual, but taking place within an interpersonal context. It involves letting go of negative thoughts, feelings, and behaviors, and their gradual replacement by more charitable ones. Forgiveness of another involves the transformation of oneself, challenging one's assumptions about the world and others, and coming to terms with reality.

### Types of Forgiveness

There are two primary ways of thinking about forgiveness: as a state and as a trait. State forgiveness is defined as the degree of positive thoughts, feelings, and intentions toward an offender, in regard to a specific instance of interpersonal conflict. Several self-report questionnaires have been developed to measure state forgiveness; individuals describe a time when they were betrayed or hurt and answer questions about

their current feelings, thoughts, and intentions toward the offender. These instruments show that the context surrounding the event plays a role in the likelihood of forgiveness. If the offender shows remorse, apologizes, and/or tries to make amends, then forgiveness is more likely. Similarly, forgiveness decreases with the severity of the event and increases with the closeness of relationship between the offender and the individual. Using these instruments, one can assess the current experience of forgiveness in relation to a specific context and measure changes over time.

The second way of conceptualizing forgiveness is as a relatively stable characteristic, that is, an individual or personality trait. Warren H. Jones and his colleagues have developed the Forgiving Personality Inventory that assesses forgiveness as a personality trait, operative across a variety of contexts. Forgiving individuals value forgiveness, have a higher threshold for perceiving offenses, and are less willing to endure the separation from relationship partners that follows from a lack of forgiveness. Ryan P. Brown has developed a measure to assess the Tendency to Forgive. He found that highly forgiving individuals recall fewer offenses and get over their conflict experiences more quickly. Kathleen A. Lawler-Row has studied the forgiving personality in adults across the age range. Highly forgiving adults have better conflict management skills; they express less anger outwardly, but are more likely to calmly confront an offender, discuss the conflict, and come to an acceptable resolution. These measures of trait forgiveness are used to determine individual differences in forgiveness and their relationship to other variables, such as age, gender, or religious commitment.

### **The Case for Forgiveness: Psychological Well-Being**

The rationale for the development of forgiveness, either as a personality characteristic or as a response to a specific event, rests on its relationship to psychological well-being and beneficial character traits. Trait forgiveness has been positively related to empathy, relationship satisfaction, and self-esteem. In addition, the tendency to forgive has been related to lower levels of anxiety, depression, hostility, rumination, narcissism, passive-aggressive behavior, and neuroticism. Thus, forgiveness has clear psychological benefits for the forgiver, even when the offender is not in a position to alter his or her behavior or to make amends.

Forgiveness has been shown to increase with age and vary with gender. Women have higher scores on trait forgiveness, while men have higher scores on state forgiveness. Among older adults, trait forgiveness is associated with several dimensions of successful aging: positive relations with others, self-acceptance, environmental mastery, purpose in life, personal growth, and autonomy. In addition, forgiveness is positively correlated with healthy behaviors, social support, and religious, existential, and subjective well-being.

### **The Case for Forgiveness: Physical Well-Being**

Forgiveness has also been shown to have physical health benefits. Highly forgiving adults have lower resting blood pressure, while state forgiveness has been associated with decreased magnitude and duration of physiological stress responses. In addition, both state and trait forgiveness have been correlated with fewer physical symptoms of illness, lower rates of smoking, and fewer medications. Statistical models indicated that these associations between forgiveness and health are mediated by existential well-being, conflict management, stress, and negative affect. Highly forgiving individuals have higher levels of existential well-being, or purpose in life, and better conflict resolution skills. People who forgive also experience less stress and less negative affect, particularly less anger, depression, and tension. When these factors are taken into account, the relationship between forgiveness and health is reduced.

### **Interventions to Help Clients Forgive**

Given the positive associations between forgiveness and psychological well-being, several interventions for helping clients forgive have been developed. Robert D. Enright was the first to study forgiveness from a therapeutic perspective; he developed a process model for increasing forgiveness and decreasing negative affect, particularly excessive anger. This model employs four phases: uncovering, decision, work, and deepening. In the *uncovering* phase, clients explore their anger and the effects it has on their lives. During the *decision* phase, clients explore their current coping strategies and consider forgiveness as an option. In the *work* phase, reframing, developing empathy, bearing the pain, and giving a moral gift are considered. Within the *deepening*

phase, clients focus on finding meaning, examining their worldview, and finding a new purpose. This model has been successfully employed with a range of client populations, and guidelines have been prescribed for applying the model to clients with depression, anxiety, substance abuse, and eating and personality disorders.

### Forgiveness in Families

Numerous events within families necessitate forgiveness. Families that report forgiveness report better individual mental health and better family functioning. Parental socialization is a significant factor in teaching forgiveness, and individuals with secure attachment styles show greater levels of forgiveness. Thus, forgiveness can be thought of as both a moral value and a coping skill that is learned through example and specific training within the family. As the family is the source of many of the offenses that one experiences growing up, this method of conflict resolution can have an impact on both the quality of family life and individual, subjective well-being.

Various interventions have explored the role of forgiveness in marriage, showing that forgiveness is related to relationship satisfaction, intimacy, and lower levels of conflict. Kristina Coop Gordon and colleagues have developed a trauma-based, cognitive-behavioral therapy for couples that have experienced a significant betrayal. The *impact* stage focuses on emotional regulation, the *meaning* stage adds insight therapy to promote greater understanding of the partner, and the *moving on* stage assesses the viability of the relationship and the couple's commitment to work toward change. Assessment of these couples shows both improved forgiveness and dyadic functioning.

### The Future of Forgiveness

Research has focused on forgiveness of others and its effects on the forgiver. Future work will seek to examine the effects of forgiveness on the forgiven and the effects of self-forgiveness. The natural history of forgiveness within the context of real-life events will be important to address the issue of whether forgiveness is always beneficial. False forgiveness, or forgiveness offered without having traversed the difficult path of arriving at genuine forgiveness, is critical to understand in developing effective forgiveness

interventions and in determining the long-term effects of forgiveness.

## FREE ASSOCIATION

---

*Free association* is an inadequate translation into English of the German term *freier Einfall* (meaning “free irruption”), which Sigmund Freud used to characterize ideas that irrupt into consciousness. Freud first described this irruption when he was investigating the causes of symptoms, parapraxes (slips of the tongue), and dreams. As a precondition of analyzing these phenomena, Freud required his patients to attend to what was being analyzed while at the same time suspending their judgment and reporting everything that came to mind. Seemingly irrelevant ideas then often forced themselves into consciousness. The candor required of the patient constituted the fundamental rule of psychoanalysis, and the patient's

reporting what came to mind was the method of free association.

The thoughts and associations reported by the patient were not complete, continuous, or orderly, and Freud assumed that the gaps pointed to unconscious psychological processes that, when discovered, could be interpolated into and complete the trains of thought that would lead to the source of the patient's conflict. Freud claimed natural science status for psychoanalysis because the interpolated unconscious processes were logically identical to the unobservable physical processes postulated in chemistry and physics.

Freud assumed that the determinants of trains of association were internal and relatively unaffected by influences external to the thinker, including unconscious suggestion from the particular analyst. Free association should, therefore, contribute to the clinical goal of building a picture of the patient's past that was essentially complete and corresponded to the patient's real history. Freud made explicit claims for the reliability and validity of the method; differences in orientation among analysts contributed only in a minor way to what patients reported and would not distort the overall picture. Suggestion from therapist to patient could be disregarded altogether.

Whether they related to a single element of a dream or symptom, a whole train of thought, or some complex aspect of a patient's history, associations had to be interpreted by the analyst. Freud set out no rules by which interpretation could be guided or judged. Nevertheless, it is clear that he valued the internal consistency of his interpretations. It was important to Freud that the elements of his interpretations were related to the phenomenon being analyzed in a coherent manner. He placed a higher value on this consistency than on the correspondence of the interpretation with the patient's past experiences.

The absence of specific guidelines for the interpretation of free associations suggests interpretations could easily be influenced by the analyst's theoretical perspectives. It is known that in clinical situations resembling psychoanalysis, patients produce material consistent with the theoretical beliefs and expectations of their therapists. Beginning in the mid-1920s with the separation of Freud and Otto Rank, and continuing through the 1960s, numerous "schools" of psychoanalysis developed, each strongly influenced by its founder's perspectives and supported by different kinds of free associations and largely incompatible interpretations.

These differences point to two fundamental problems: the low reliability and validity of free association, and the basic indeterminacy of interpretation. It is clear that associations are not as free of external influence as Freud believed. Nevertheless, very few analysts have questioned the reliability or validity of free association or raised the problem of the indeterminacy of interpretation. It is also clear that the clinical situation is a very difficult arena from which to gather data that leads to good theories about patients and clients.

## FREUD, SIGMUND (1856–1939)

---

Sigmund Freud wanted to show the importance of a force outside of everyday experiencing that we cannot know directly which governs our actions—the unconscious part of the mind. According to Freud, the *unconscious* is the source of wishes arising in childhood that are socially reprehensible and blocked from consciousness. We can only be certain of the unconscious because wishes regarding intimacy with caregivers that emerge in the preschool years attempt partial satisfaction, disguised as slips of the tongue or dreams. Freud relied both on the force of his argument as a distinguished scientist and on his autobiography in demonstrating that there is an unconscious. If he had used reports by his clients, his theory might have been dismissed as the accounts of troubled persons. Further, considerations of confidentiality limited the

detail he could provide from his clients' accounts. For this reason, to understand his theory it is particularly relevant to know about Freud's history.

Sigismund Freud, as he was called in his youth, was born in the Austrian Empire, in what is now the Czech Republic. He was the firstborn son of Amalia Nathansohn, a woman 20 years younger than her husband, and Jacob Freud, an impoverished wool merchant who had two grown sons, Emmanuel and Philipp.

### Early Developmental Influences

Emmanuel had two children, John and Pauline, who were close to Freud's age. In a 1899 paper on *screen memories* (i.e., memories of early life experiences that presumably are a cover for even earlier psychologically significant memories that are censored from awareness because they are more painful), Freud described an incident in which he and John, rivals for Pauline's attentions, snatched away the bunch of yellow flowers Pauline was picking in a mountain meadow. He connected this incident with the early awakening of his sexuality. (Freud reports that a yellow flower was the only one that he had difficulty identifying on his medical school examination, an instance of a "neurotic inefficiency.")

Freud's parents had eight children. Freud's next youngest brother, Julius, and his mother's brother Julius both died as young Freud approached his second birthday. His mother was emotionally preoccupied with mourning her losses and transferred Freud's care to a succession of governesses. When Freud was 2½ years old and still acutely suffering the loss of his mother's emotional support, he lost this favorite governess, who was arrested for petty theft. When Freud was 4, his father decided to move the family to Vienna. Biographer Peter Gay recounted that years later, while in the midst of his self-analysis following his father's death, Freud recalled that he had shared a bedroom on the train with his mother and saw her naked while preparing for bed. The wish stimulated by this encounter, together with the social prohibitions against awareness of this wish, led Freud to experience anxiety which was displaced onto train travel, and this accounts for Freud's lifelong phobia of train travel.

It is striking how much these early childhood experiences shaped Freud's writing and clinical technique. Mothers are almost always missing from Freud's most well-known case studies. Further, Freud insisted that personality development does not begin until sometime

between ages 3 and 5. At this age the little boy experiences rivalry with his father for the attention of his mother, and the little girl experiences rivalry with her mother for her father's attention. Freud devoted little study to the quality of the very young child's tie to his or her mother.

After World War II psychoanalysis followed developmental psychology into the detailed study of the child's attachment and the course of the mother-child relationship. At this point Freud's daughter Anna, the "gatekeeper" of psychoanalysis following her father's death, observed that her father's theory emphasized problems arising from conflicting wishes and desires arising during the preschool years rather than the experiences of earliest childhood. It would appear that Freud never completely resolved his grief following his emotional loss of his mother. Further, Freud's case studies are replete with incidents in which governesses contributed to the client's later distress.

### Freud's Education

Freud excelled in his studies in Vienna and entered the Gymnasium, or academic high school, which emphasized instruction in the classical languages. He learned to read, write, and speak many European languages, as well as English, and would have liked to become a classical scholar. His father explained he couldn't afford to support Freud's graduate studies, and that "denominational" concerns (the family was Jewish) would prevent Freud from obtaining a university professorship. At that time all such appointments were approved by the government education ministry, which opposed the appointment of Jewish scholars. The collapse of the Hapsburg monarchy in 1867 marked the end of a socially and politically liberal period in Vienna and the emergence of the anti-Semitism that overspread Europe in the 20th century.

Inspired by an essay on natural philosophy, Freud entered medical school at the University of Vienna. It was there that Freud met physician Josef Breuer, the "doctor's doctor" to the medical school faculty, who had returned to medical school to learn the new physiological psychology. Breuer became Freud's mentor in medical school, and helped to pay for his medical studies. Despite the pragmatic decision to pursue a career in which he could expect to find employment, Freud's scholarly interests are reflected in the fact that he took 8 years rather than the usual 5 to complete his degree. He filled his extra time by reading Aristotle's

metaphysics with the renowned philosopher-psychologist Franz Brentano and conducting research on issues that today would fall into the discipline of developmental neurobiology in Ernst Brücke's laboratory. Breuer became Freud's mentor in medical school, and in the late 1880s, when Freud was becoming the preeminent neurologist in Central Europe, they collaborated on the psychotherapy of hysteria.

Freud married Martha Bernays and settled into a comfortable apartment at 19 Bergasse (Mountain) Street in Vienna, on the road leading to the university and the medical school. The Freuds had six children, the youngest of whom, Anna, became an internationally renowned child psychoanalyst. She continued as the most important figure in psychoanalysis from her father's death in 1939 until her own death in 1983.

### Oedipus Complex

Freud's collaboration with his mentor, Josef Breuer, from 1886 to 1893, on the innovative psychotherapy of hysteria focused on the psychological meaning of symptoms rather than posthypnotic suggestion. Their 1895 book, *Studies in Hysteria*, reported on their clinical studies, but by that time, Freud had ended his friendship with Breuer. While Breuer maintained that the origin of hysteria was based on a set of associations split off from consciousness, Freud posited that hysterical symptoms were used as a defense to prevent the individual from becoming aware of desire that conflicted with prevailing social standards.

A striking feature of Freud's psychotherapy of hysteria was his observation of a nearly universal recollection of a father's seduction of his daughter during early childhood. In an 1897 letter to his confidante, Wilhelm Fliess, Freud suggested that this seduction may not be a reality, but rather a universal fantasy of early childhood arising from the daughter's wish for intimacy with her father. Freud's father had died in October of the preceding year, at age 81, and Freud was propelled into an introspective self-analysis, discovering that the father whom he loved was also a rival for his mother's love. Freud believed that this family dilemma was analogous to that in Sophocles' trilogy of plays about Oedipus. His self-analysis enabled him to discover the significance of dreams as disguised or socially acceptable expressions of the *nuclear wish* (later called the *Oedipus complex*) that arises during the preschool years. This wish arises in the aftermath of the triangular conflict of love of the

opposite-gender parent, and rivalry for this parent for the love with the parent of the same gender. The nuclear wish is always pressing for satisfaction, but it is socially unacceptable and therefore is repressed to keep it out of consciousness.

*The Interpretation of Dreams*, published in 1900, is the masterpiece of the 23 published volumes of Freud's work. In this book, he depicted the nuclear wish (the Oedipus complex) as the determinant of all mental life. Over the succeeding decade, Freud argued that many aspects of the personality were *compromise formations* whose function was to provide at least partial satisfaction of the nuclear wish while shielding the individual from awareness through repression. In addition to dreams, compromise functions included fears, phobias, hysterical and obsessive afflictions, works of art, so-called unintentional actions such as slips of the tongue, and all human relationships, including the relationship with the analyst.

### Freud's Topographic Model

Freud's first *topographic* model of the mind depicted variations in the individual's level of awareness from unconscious to consciousness. Freud maintained that this model explained attention; what we notice at any moment is determined by the effort to satisfy wishes originating in childhood desires. These desires always remain out of awareness but always seek satisfaction. Freud believed that all thought is ultimately determined by aspects of the personality that lie outside the range of consciousness.

From 1905 to World War I, Freud developed his model depicting the mind as motivated by the need to defend the individual against the awareness of socially unacceptable wishes and intents. Freud was invited in 1909 to Clark University in Worcester, Massachusetts, where he delivered five lectures that systematically portrayed the model of the mind he first portrayed in *The Interpretation of Dreams*. The case reports and essays he published in the years before World War I elaborated his model to show that, in addition to dreams, so-called unintended actions (or the psychopathology of everyday life) and psychological or psychoneurotic symptoms also represented disguised satisfaction of the nuclear wish. Freud's topographic model was most fully portrayed in the lectures he delivered to a mixed medical school and lay audience (with then-educator-daughter Anna in attendance) in the winter terms of 1915–1916 and

1916–1917. The lectures were later published as the *Introductory Lectures on Psycho-Analysis*.

### Illustrations From Case Reports

The concept of *repression* as the determinant of consciousness was demonstrated in Freud's case reports, such as his 1909 *Analysis of a Phobia in a Five-Year-Old Boy*, in which Freud described "Little Hans," the son of one of his early collaborators, who had developed a phobia about going out in the street. The power of the nuclear wish as a cause of hysteria was shown in his 1905 *An Analysis of a Case of Hysteria*, a failed analysis of Dora, a so-called hysterical young woman. Only in retrospect did Freud realize his own contribution to his conflicted relationship with his patient. Freud's report of his work with Dr. Ernst Lanzer (the "Rat Man"), in his 1909 *Notes Upon a Case of Obsessional Neurosis*, described a brief analysis of a man with obsessive symptoms who died tragically in the first days of the war. Freud's notes on his sessions with Lanzer are the only published record of how Freud worked during that time. In his 1918 *From the History of an Infantile Neurosis*, Freud reported on his work with Sergei Pankejeff, a Russian nobleman Freud described as the "Wolf Man," a name inspired by Pankejeff's childhood dream featuring still white wolves on a tree outside his parents' bedroom. Freud also wrote a psychobiography based on the 1911 book *Memoirs of My Nervous Illness* by Daniel Schreber, a troubled German jurist struggling with his paranoid feelings regarding his punitive father (inventor of the first gym "workout" machines). His detailed 1910 psychobiographical study *Leonardo da Vinci and a Memory of His Childhood* showed how the censored nuclear wish could appear in a culturally valued or sublimated form.

### Psychoanalysis

With the translation of *The Interpretation of Dreams* into English and the critical acclaim for this epochal study and other papers published before World War I, European and American physicians and intellectuals flocked to Vienna to learn from Freud. First meeting as a regular Wednesday evening discussion group, these meetings were the foundation of the Vienna Psychoanalytic Society and, later, the International Psychoanalytic Association. During these interwar years, Freud's work garnered international recognition

and he was awarded numerous prizes for scientific achievement.

In his papers on the theory of psychoanalytic technique or method, written between 1911 and 1915, Freud discussed issues in the relationship of analyst and client. He further developed the concept of the *transference* (or displacement) of affections from earliest childhood to the analyst as a transference neurosis. Freud viewed transference as the experiencing of desires that are stimulated by the process of psychoanalysis. Freud warned of the dangers inherent in the analyst's response to the expression of the patient's loving feelings. He regarded these as the replay of childhood desire now displaced on to the analyst. He highlighted the importance of reliving or working through and putting to rest these unrequited desires and other remembered feelings and experiences. Freud identified forces in the psychoanalytic encounter that assist the process of working through and resolving childhood experiences and memories and those that create resistance to working thorough and resolving neurotic conflict. Falling in love with the analyst and tenaciously refusing to understand the basis of this desire provides at least partial satisfaction of the nuclear wish of childhood in the same manner as slips of the tongue, dreams, psychoneurotic symptoms, and sublimations. Clients inevitably experience resistance both to the awareness and to the resolution of this transference neurosis.

Following World War I, Freud turned his attention to the study of psychoanalysis and the necessity and discomfort inevitable in social life. This concern led Freud to revise his prewar topographic model of the mind. In 1923, Freud revised his theory to feature three interrelated personality structures: self, desire, and external social prohibitions and moral standards, translated from the German as ego, id, and superego. This model portrayed personality as driven by desires emanating from the unresolved nuclear conflict of the preschool years. The *id* demands immediate gratification of every desire, the *superego* demands that moral authority be obeyed, and the *ego* attempts to mediate these expectations to comply with the demands of the real world.

Freud managed his writing and clinical work from 1923, on even as he struggled with cancer. In 1938, following the German annexation of Austria, Freud's friend, Princess Marie Bonaparte, directly interceded with Hitler on behalf of the Freud family, and the Freuds journeyed into exile in England. Freud died in London in September 1939.

## Conclusion

Freud's contributions to the study of mental life have continued to inform psychoanalytic technique and to provide innovative perspectives for study in the human sciences and the humanities. Psychoanalysis is now recognized both as a "one-person" or intrapersonal psychology and as a relationship or "two-person" psychology in which the analyst's personality and experiences become a part of the collaboration to help the client gain greater self-understanding and resolve neurotic suffering. Freud's legacy is that of compassionate concern for human welfare and profound wisdom concerning the human condition.

The founder of psychoanalysis occupies a unique although controversial position in psychology. Psychoanalysis is both an approach to understanding motivation and a systematic approach to psychotherapeutic intervention. Challenged by a variety of alternative psychotherapies from within both psychology and biological psychiatry, contemporary psychoanalysis has redoubled efforts at systematic study of the technique of clinical psychoanalysis. This inquiry includes the relationship between analyst and client, study of the interplay of biological substrate and personal distress, and process and outcome studies focused on the long-term success of psychoanalysis.

Few founders of intellectual perspectives have been as venerated and disparaged as Freud. Freud adopted the term *ambivalence* from Swiss psychiatrist Eugen Bleuler's to refer to the concurrent positive and negative emotional attitudes of children toward their parent of the same sex. This ambivalence characterizes both lay and public attitudes toward the founder of psychoanalysis. Nearly 70 years after Freud's death, many published papers in the psychoanalytic literature begin with a review of his work on their topic before proceeding to more recent commentary and perhaps a case formulation. The popular press continues major stories regarding the significance of Freud's legacy with pronouncements that psychoanalysis is (or is not) dead as an intellectual discipline and method of psychotherapy.

## **GAY, LESBIAN, AND BISEXUAL THERAPY**

---

In most cases, gay, lesbian, and bisexual (GLB) clients seek out counseling and therapy for the same reasons that heterosexual clients seek services, including relationship and family issues as well as concerns about work and social stressors. However, several therapeutic concerns specific to GLB sexual orientation include coming out and sexual identity development; anti-GLB and heterosexist attitudes, prejudice, and discrimination; and GLB relationship and family issues. Therapists who are of any sexual orientation can be effective working with sexual minority clients as long as they are knowledgeable about GLB therapeutic concerns and are relatively free of heterosexist assumptions and biases.

### **Coming Out and Sexual Identity Development**

#### ***The Process of Coming Out***

*Coming out* is a term used to describe the disclosure of one's sexual orientation to others (e.g., family, friends, coworkers), either by identifying as GLB or by indicating a same-sex relationship or orientation. Someone who has not disclosed his or her GLB orientation either with significant others or at work is often referred to as being "in the closet." Coming out is not a one-time occurrence, rather it is a process that GLB individuals have to grapple with each time they meet someone new or enter an unfamiliar environment. When thinking about coming

out, GLB individuals often consider issues of safety and acceptance; for some, coming out could mean risking their employment or family relationships. Because it is commonly assumed that people are heterosexual, GLB people consider coming out important for conveying a sense of who they are, and this goes beyond sexual attraction and desire. Individuals range in their comfort with coming out. For some, disclosing sexual orientation is a natural process; however, for others, particularly when they are first gaining awareness of their same-sex attractions, it can be a challenge and may become a central focus of therapy. For example, some university counseling centers provide coming out groups, and many therapists will help clients practice coming out to others or even facilitate coming out to family members as part of the therapeutic process.

Research suggests that it can take as many as 9 years for individuals to come out to themselves and their significant others, and for some who live and work in extremely heterosexist environments, coming out as GLB is not a safe option. Typically, GLB clients come out to friends first, followed by supportive siblings, mothers, and finally, fathers. Although reactions to coming out differ in each situation, self-disclosure often sets off a response similar to other ways a family has responded to crisis or change. Individuals close to a GLB person will have their own coming out process as they integrate new information and wrestle with their own self-disclosure issues.

#### ***Sexual Identity Development***

The process by which individuals become aware of their same-sex attraction and subsequently identify as

GLB is referred to as *sexual identity development*. Many different developmental sexual identity models have been proposed, and while they can serve as useful guidelines for understanding a client's experience, they do not capture the complex and distinct ways individuals come to understand and express their GLB sexual identity. Vivian Cass and Richard Troiden first introduced stage or phase models of sexual identity development in 1979. Numerous models followed, and while each had its own perspective, they shared several common themes. The first phase is characterized by feelings of being socially different from heterosexual peers, which are often accompanied by strong feelings of isolation and fear. Clients at this phase may not be aware of their same-sex attractions, and often will present in therapy with depression, loneliness, and illnesses. The focus of therapy is to treat symptoms rather than emphasize sexual identity concerns.

When same-sex attraction begins to have some personal relevance, a person may be in phase 2, characterized by private labeling of feelings as possibly "not heterosexual." Such awareness can lead to extreme confusion, and some will seek therapy to work through their feelings of grief and loss of heterosexual privilege. Clients at this point are struggling with stereotypes and negative internalized messages about homosexuality as they attempt to integrate an new understanding of themselves. It is vital for therapists to not rush the sexual identity process and to match the clients' pace, particularly with how they choose to describe themselves.

As clients enter the third phase, they find an identity label that more accurately describes their affectional and sexual attractions than the term *heterosexual* does. They have moved into understanding themselves as probably GLB rather than possibly not heterosexual; therefore, appropriate referrals to positive role models and community support are of particular importance. They may begin to see themselves as belonging to a GLB community, even if peripherally, and socializing with other GLB individuals is more common. Many clients find themselves experiencing a new adolescence in which they feel as if they are starting over with dating and having strong emotional attachments perhaps for the first time. It is important for therapists to provide clients with continuity of identity exploration and facilitate healthy self-disclosure.

When contacts with GLB community members are positive, clients may move into phase 4. At this point they accept, rather than simply tolerate, their sexual

identity and begin an active social life. Clients may begin to label themselves as GLB, and the therapist may begin to use the language the clients use to describe themselves. Often, individuals in therapy are beginning relationships during this phase and may seek support for navigating as a new couple. Learning to self-disclose selectively and with appropriate language is also central in this phase. Sometimes clients begin to experience a great deal of distrust and anger over their position as GLB individuals in a heterosexist society. They may sever ties with heterosexual family and friends, and engage in dichotomous "us vs. them" thinking. However, as GLB individuals are met with affirming heterosexual allies and the diversity of the GLB community, they may begin to revise their philosophies by learning to trust and depend on others based on qualities other than sexual orientation. Additionally, they may deepen their understanding of their sexual identity as merely one aspect of their lives and not the central focus. Final stages of sexual identity development are characterized by a synthesizing of GLB identity with other aspects of self, in which sexual orientation is not the only defining quality of personality.

### **Anti-GLB and Heterosexist Attitudes, Prejudice, and Discrimination**

Although GLB individuals have advanced a great deal in terms of equal rights in the past decade, heterosexist attitudes and actions continue to create challenges for GLB individuals. For example, in some states, GLB individuals can be fired simply for disclosing their sexual orientation. In most states, there is still no protection for sexual orientation for equal housing or public services. Similarly, except in Massachusetts, GLB individuals in the United States cannot marry their same-sex partners, which limits their access to over 1,300 federal benefits, including hospitalization rights, tax benefits, and family rights. In addition, through adoption prohibitions and fertility treatments limited to married couples, there is systematic discrimination of GLB individuals who wish to create families. GLB people are more at risk for violent hate crimes, and Gregory Herek's research has shown that on average it takes 5 years to recover from a targeted attack due to one's group membership rather than the 2 years that typically is required for a person to recover from a random act of violence. As GLB individuals encounter discriminatory practices or crimes

targeted against them, they may present in therapy with issues of anxiety, depression, hopelessness, and even posttraumatic stress disorder. It is important that therapists be aware of the legal issues that GLB clients face and have appropriate referrals for legal advice and planning.

## Relationship and Family Issues

### *Social Support*

GLB individuals and couples receive less social support than do heterosexuals from their families of origin; however, they tend to report feeling satisfied with their overall level of social support. While it is true that many GLB individuals experience conflict and disruptions in their families upon coming out, for the most part GLB individuals remain in connection with their families of origin. In order to counterbalance the lack of support from families of origin, GLB people often create families of choice, a close-knit group of friends who serve in every function as family. Such constellations of support are important for therapists to keep in mind as they explore family dynamics and social support. Even if GLB clients do not report that they have close families, it cannot be assumed that there are not close networks just as vital to the client as blood relatives. Therapists should be cautioned against focusing on fragmented family-of-origin relationships at the expense of other more central systems of social support. Nevertheless, it is important to not discount that families of origin may not be providing support to GLB individuals.

### *Relationship and Parenting Issues*

Besides structural and legal obstacles to creating GLB families, many couples struggle with acceptance of their families. While GLB relationships are reported to be just as relationally and sexually satisfying as heterosexual relationships, there are few supports for same-sex relationships. Same-sex couples are often not provided with spiritual or religious recognition, and many have to form their own spiritual communities. Individuals in a same-sex couple can come to the relationship with differing experiences of coming out and sexual identity development, as well as internalized *homophobia* (the degree to which GLB individuals adopt negative attitudes and

beliefs about homosexuality). Such internalized homophobia can negatively impact the couple relationship in numerous ways, including sexual satisfaction and intimacy, as well as communication and trust.

GLB parents, in particular, are vulnerable to heterosexism. Even though the 2000 Census revealed same-sex couples living in 99% of counties in the United States, and 55% of these couples reported raising children, same-sex partners are rarely allowed to both be full legal parents due to the limits of second-parent adoptions (only available in select cities and jurisdictions) and laws denying two parents of the same sex to be listed on birth certificates. When GLB families encounter difficulties such as relationship separation or death of a partner, they are often faced with no legal support for resolving custody issues or no legal rights to children whose parents they are in every way but in the eyes of the law. Therapists can help by acknowledging the negative impact of such extant laws on clients, supporting clients to seek GLB-affirmative legal support, and advocating for equal family rights for GLB individuals.

## GELSO, CHARLES J. (1941– )

---

Charles J. Gelso, who was born on November 27, 1941, in Pittston, Pennsylvania, has been a professor of counseling psychology at the University of Maryland for most of his career. He is the author of more than 110 articles in professional counseling journals, as well as 10 book chapters and 4 books. His scholarship addresses issues such as the research training environment, time-limited counseling, research methodology, and the psychotherapy relationship. His articles on research methodology and the psychotherapy relationship, in particular, are among the most frequently cited writings in the field of counseling psychology. Gelso was the editor of the *Journal of Counseling Psychology* from 1982 to 1987, and in 2005 he began a term as the editor of *Psychotherapy* that will run through 2009. He is a Fellow of the American Psychological Association, the American Association of Applied and Preventive Psychology, and the American Psychological Society. He received the 2003 Distinguished Psychologist Award from the American Psychological Association's Division of Psychotherapy, and the 1996 Leona Tyler Award for career achievement in, and outstanding contributions to, the field of counseling psychology from the American Psychological Association's Society for Counseling Psychology.

### Research Methodology

Gelso developed a taxonomy for classifying and thinking about counseling research. According to this taxonomy, counseling research can be categorized as occurring in the field or in the laboratory, and variables can be experimentally controlled or naturally observed. Research that is conducted in the field has *high external validity* (i.e., its results generalize more readily to actual counseling than research conducted in the laboratory). Studies in which the researcher exerts experimental control by manipulating independent variables allow for causal statements to be made about the effects of the independent variable(s) on the dependent variable(s). Such studies are said to have *high internal validity*.

Gelso noted that each type of research has advantages and disadvantages and that no study is perfect. This last idea he called the *bubble hypothesis*, likening it to the notion of an air bubble that gets caught under a windshield sticker. One can move the bubble

around but not eliminate it entirely. Similarly, researchers can try to correct for the flaws that exist in previous research on a topic, but they can never remove all of the flaws in any one study. In short, a perfect study cannot be conducted.

### The Psychotherapy Relationship

Gelso conceptualized the relationship between the therapist and client as consisting of the *working alliance*, the *real relationship* (i.e., clients' and therapists' realistic perceptions of each other and the extent to which each is authentic with the other), *transference* (i.e., the client's unconscious redirection of feelings and personal issues onto the therapist), and *countertransference* (i.e., the projection of therapists' unresolved personal issues onto the client). Gelso and his colleagues developed a measure of the real relationship that allowed research to be done in this area. His systematic program of research on countertransference identified factors that contribute to countertransference, the effects of countertransference on the therapy process, and strategies therapists can use to manage their countertransference reactions.

## GOLDBERG, LEWIS R. (1932– )

---

Lewis R. Goldberg is an internationally acclaimed psychologist best known for his programmatic studies testing the lexical hypothesis that any culturally

important personality characteristic will be represented in the language of that culture.

Goldberg was born in Chicago on January 28, 1932. As an undergraduate at Harvard (1949–1953), he decided against following his father into the legal profession and majored in social relations. Although interested in quantitative methods, he pursued graduate study in the University of Michigan's psychoanalytically oriented clinical psychology program (1953–1958). Luckily for him (and the field of personality measurement), E. Lowell Kelley, the one member of that program with a quantitative orientation, became his adviser and dissertation director. Kelley provided Goldberg the opportunity to study the quantitative personality assessment techniques for which he has become so well known.

As an advanced graduate student at Michigan, Goldberg met Warren T. Norman, a new assistant professor, who became a lifelong friend and collaborator. Following a 2-year appointment as an assistant professor at Stanford, Goldberg went to the University of Oregon and the Oregon Research Institute where he continues to produce fundamental research in personality assessment. In his early years at Oregon, he served as a field selection officer for the U.S. Peace Corps beginning during a period when Kelly was serving as its director of selection. He has been president of the Society of Multivariate Experimental Psychology and of the Association for Research in Personality. He is a fellow of the American Psychological Association, the American Psychological Society, and the American Association for the Advancement of Science. In 2006, he won the Jack Block award for Personality Research from the Society of Personality and Social Psychology.

A long history of research in psychology has demonstrated that the thousands of adjectives used in everyday language to describe variations among people actually refer to a relatively small number of dimensions. Norman replicated this research with peer ratings and introduced Goldberg to these issues at Michigan. With students and colleagues, Goldberg tested the lexical hypothesis by examining the robustness within and across cultures of five factors (which he dubbed the "Big Five") composed of adjectives used in rating self and others. Collaborating with researchers around the world, Goldberg and his students and colleagues have examined the similarities and differences in the multidimensional organization of adjectives used to describe stable characteristics of personality. This work has been done using both

Indo-European and non-Indo-European languages. Most recently, Goldberg and Sarah Hampson analyzed data collected by his colleague John Digman to examine the longitudinal consistency of personality ratings over 40 years.

Three hallmarks of Goldberg's research are the depth with which he examines fundamental problems in assessment, the openness with which he shares the results, and his willingness to collaborate with one and all. Perhaps the best example of all three of these tendencies is his remarkable "collaboratory." This International Personality Item Pool (IPIP) makes available to all researchers a pool of more than 2,000 items and 250 carefully constructed scales that measure the plethora of constructs associated with particular proprietary instruments. The item pool uses short phrases instead of adjectives to better capture the nuances of personality. Validity information for the scales are derived from a longitudinal study of a sample of community volunteers in Eugene, Oregon, who completed the IPIP items and commercial inventories measuring traits, interests, values, and activities.

## GOLDMAN, LEO (1920–1999)

---

Leo Goldman gave critical attention to the use of psychological tests in counseling. As editor of the *Personnel and Guidance Journal*, he emphasized the importance of educating counselors in the use of psychological tests. He was skeptical of the value of

standardized tests and concerned with the potential misuse of test information in the public school system. Following a critical review of the literature in 1972 titled "Tests and Counseling: The Marriage That Failed," Goldman concluded that a meaningful relationship between testing and counseling practice was in doubt. He questioned whether and how counselors can derive functional utility from testing and measurement, beyond understanding the technical characteristics of the instruments used. Goldman advocated alternative assessment approaches found in qualitative methods, and he also argued for the use of qualitative research methods.

Goldman's proposals for qualitative assessment and qualitative research became in the next decade a more radical call for counseling psychologists to consider alternative research paradigms. In his 1976 article titled "A Revolution in Counseling Research," Goldman became one of the first to advocate for a paradigm change in counseling research. Goldman viewed the limitations of standardized testing as part of the limitations of the quantitative research paradigm that has dominated the field of psychology. Measurement-driven research utilizes psychological tests that have demonstrated reliability and claims of validity. Standardization as a scientific norm upheld in the test and measurement industry has been shared by the experimental tradition in psychology. These paradigmatic values and practices constitute the context of test development and test usage, and for Goldman, the basis of his criticism of them.

Goldman also expressed concern about the needs of minority populations and argued that professional practice including assessment approaches must take into account their needs. He viewed the issue of validity in testing as part of the increasing awareness of cultural factors in assessment and counseling interventions. The issue of cultural validity in standardized test use was more than an epistemic issue for Goldman; it has implications for social justice. In his 1990 presidential address to APA Division 17 (Society of Counseling Psychology), titled *Participants and Gatekeepers*, Goldman called for more inclusiveness in the counseling profession. Consistent with methodological pluralism in research, he argued for practice-oriented methods of assessment and a culture-sensitive professional practice that is inclusive of diverse groups.

The influence of Goldman's work is seen in recent contributions that reflect the counseling professional's role in testing, and counselors as consumers of test

information. The relevance of test information to counseling and inquiry continues to be important to practitioners and researchers. Issues of validity and cultural bias are intertwined with the social and political uses of testing, issues that were anticipated in Goldman's critical perspective and the moral vision that he provided in his autobiographical 1998 essay, "Still the Serendipitous Maverick."

## GROUP THERAPY

---

Group therapy is a form of psychotherapy where one or more therapists treat a small group of clients together. Group therapy, like individual psychotherapy, is intended to help people who would like to improve their ability to cope with difficulties and problems in their lives. The therapist uses the emotional interactions of the group members to help them get relief from distress and modify their behavior. The aim of group psychotherapy is to help with solving the emotional difficulties and to encourage the intra- and interpersonal development of the participants in the group. At least 3, and usually more, group members are necessary to establish the critical mass that allows the types of interactions that give the psychotherapy group its unique character. From 6 to 10 members is considered an ideal number, and 13 or more are too many. With too many members, it is impossible to

create a therapeutic atmosphere and have enough time for each member to work personally. The group meets regularly at stated intervals, usually once a week, for a specific period of time, for the purpose of bringing about psychological change in the group members. The length of each session can be from 1½ hours to 3 hours. The duration of the group—from a few months to a few years—depends on many components, such as the severity of the problems and the outcome goals sought. Having a designated leader is an essential aspect of group therapy.

### **Types of Groups**

Group psychotherapy and group therapy are often used synonymously with group therapy being the colloquial and shortened version. Group therapy is also used on occasion to represent a broader category of group work. In addition, some practitioners use the terms *group counseling* and *group psychotherapy* interchangeably. However, position statements issued by the Association of Specialists in Group Work (ASGW) of the American Counseling Association (ACA) have defined the terms as two different entities with group psychotherapy being one of four distinct group types: task groups, psychoeducational groups, counseling groups, and psychotherapy groups.

### **Task and Counseling Group Focus and Goals**

Task groups are designed to accomplish identified work goals. They include committees, task forces and social action groups, study circles and learning groups, planning and discussion groups, and other group experiences where the participants have a task to accomplish that is external to the individual members. Psychoeducational groups provide participants with information, skills, and increased awareness of some life problem and the knowledge and tools to better cope with it. The goal is to prevent various psychological problems and educational deficits by imparting, discussing, and integrating factual information.

Counseling groups are very similar to therapy groups. However, counseling groups are not concerned with the treatment of more severe behavioral and psychological disorders. The main differences between psychotherapy and counseling groups is that counseling groups are not aimed at major personality changes; they deal primarily with conscious

problems and they focus on resolving specific short-term concerns.

### **Psychotherapy Group Focus and Goals**

The psychotherapy group, more than other types of groups, is designed primarily to help individuals with chronic or acute emotional or mental disorders that produce marked distress and impairment. The group allows individual group members to reconstruct major personality dimensions and remediate in-depth psychological problems. Thus, psychotherapy groups focus upon addressing personal and interpersonal problems of living, modifying perceptual and cognitive distortions, reducing repetitive patterns of dysfunctional behavior, and promoting personal and interpersonal growth and development among participants who are experiencing severe or chronic maladjustment. Psychotherapy groups allow for the development of appropriate group norms and task elements necessary to support the intensity of the social and emotional interaction that promotes change. While conceptualized, composed, and conducted as an intervention to deal with those needing intense interpersonal work to modify major psychological dysfunctions, it can also provide attention to interpersonal problem solving and to psychoeducational information and skill acquisition as a part of the overall therapeutic group experience.

Psychotherapy groups provide a safe environment in which group members can experiment with new ways of looking at life, experiment with new behaviors, and offer a powerful opportunity for positive change. Even though group psychotherapy frequently focuses on participants with severe problems, the scope of group psychotherapy is extremely broad. Psychotherapy groups are used to treat individuals with mild to moderate personality problems, interpersonal conflicts, and neurotic disorders. Psychotherapy groups are especially helpful in improving interpersonal relationships, although evidence suggests they are quite useful for anxiety and depression. Groups are ideally suited to people who are struggling with issues like intimacy, trust, and self-esteem. The group interactions help the participants to identify, get feedback on, and change the patterns that are sabotaging their relationships outside the group. The great advantage of group psychotherapy is working on these patterns in the “here and now”—in a group situation similar to members’ reality and close to their interpersonal

events. Members learn how they can achieve more happiness in general and how to create meaningful, supportive, and loving relationships with others. Groups also create a setting where, through seeing others who are struggling with similar concerns, participants find their issues normalized, and through seeing others succeeding, participants are given hope.

### Varieties of Psychotherapy Groups

Group psychotherapy is based on the fact that mental dysfunction and emotional illness can be relieved through the psychological effects of several people upon one another. Improvement in mental functioning tends to alleviate psychological distress and may eventually alleviate mental illness. This has inspired numerous efforts to utilize the healing force of the group to meet the therapeutic needs of a wide range of clients—individuals at all phases of the life cycle with highly diverse problems needing treatment. Simultaneously, virtually all schools of psychotherapy have embraced group practice and have attempted to incorporate their respective conceptual frameworks into group work. As a result, group psychotherapy is not based on a single theoretical perspective, but takes from many theories what seems to be most helpful. The techniques used in group therapy can be verbal, expressive, psychodramatic, and so forth. The approaches can vary from psychoanalytic to behavioral, from Gestalt to encounter, from existential to rational. Each approach has its advantages and drawbacks.

Groups differ not only in their theoretical approach, but also in their focus and application. Some of these differences may be based on the therapist's general orientation and specific approaches; the goals of the treatment; the subjects of the treatment, including problem areas and client characteristics; setting; and the time and duration components of the group.

Groups can be categorized as either small or large, short term or long term, outpatient or inpatient, ongoing or time limited. Psychotherapy groups can be open groups or closed groups. *Open groups* replace members as they drop out or terminate. *Closed groups*, after a period of forming, do not allow new members to join. Psychotherapy groups can be heterogeneous or homogeneous. *Heterogeneous* groups have members with quite different presenting diagnoses, complaints, or life problems. *Homogeneous* groups are made up of people with the same presenting diagnosis, complaint, or life problems. Usually psychotherapy groups are

composed of individuals who do not have preexisting emotional ties to each other, although couples may become a part of a group of unrelated persons or may join other couples in a couples' group. Families also may be treated using a group modality—referred to by names such as multifamily group psychotherapy, family group consultation, and others. Some psychotherapy groups focus on a specific area of common concern, such as relationships, anger, stress-management, and so forth. These groups often have an educational or teaching component and are frequently more time limited than general process-oriented psychotherapy groups. These homogeneous groups are especially beneficial for providing support, normalizing the concern, and encouraging modeling of participants who are successfully addressing their issues.

Group therapy is also used in psychiatric hospitals, general medical hospitals, and outpatient clinics to help clients deal with the psychological impact of terminal illness, cancer, attempted suicide, and stress. Individuals with profound ego impairment can be treated in psychotherapy groups in hospital groups, post-hospital follow-up groups, and day hospital groups. Group psychotherapy is extremely helpful as a part of an overall institutional treatment program in combination with psychological medication, individual therapy, and milieu therapy. Large psychotherapy groups are usually conducted in community or institutional settings, and such groups are often organized to work on a specific problem—for example alcoholism, obesity, rehabilitation, or another area of concern.

### Outpatient Therapy Group Process

The prototypical psychotherapy group is the open, heterogeneous, outpatient group that meets weekly for 6 months or more, admitting new participants as necessary to maintain a critical mass. The group therapist, leader, or facilitator chooses as candidates for the group those people who can benefit from group interaction and who are likely to have a useful influence on other members in the group. Most screening and selection procedures are subjective and rely on the intuition and judgment of the group leader. Usually, a moderate amount of social ability and psychological-mindedness, along with some commitment to change interpersonal behaviors and some positive expectations about the benefits of group treatment, are considered important for participation in a group. Certain

individuals are less likely to benefit. These include people who are extremely self-centered, acutely psychotic, highly paranoid, or actively suicidal, or extremely aggressive and hostile people, with a tendency to act out.

Group psychotherapy is the deliberate effort to alter the feelings, thinking, and behaviors of group members. In group therapy, past experiences, experiences outside the therapeutic group, and especially the interactions between the members of the group and the therapists become the material for the therapy. Frequently, the people in the group represent others in participants' past or current lives with whom they have difficulty. Essentially, the problems that the clients experience in daily life will also show up in their interactions in the group, allowing the problems to be worked through in a therapeutic setting, generating experiences and behaviors that may be transferred back to life outside the group.

Members of the group share with the others in the group personal issues that they are facing. Participants can talk about events they were involved in during the week, their responses to these events, and the effectiveness of those responses. Participants can share their feelings and thoughts about what happened in previous sessions, and relate to issues raised by other members or to the leader's words. Other participants can react to words and behaviors, give feedback and encouragement, provide support or criticism, or share their thoughts and feelings following interactions. The leader does not determine the subjects for discussion, as subjects rise spontaneously from the group. The members in the group feel that they are not alone with their problems, and they discover that there are others who are experiencing similar issues. The group can become a source of support and strength in times of stress for the participant. The feedback they get from others on behavior in the group can make them aware of maladaptive patterns of behavior. At that point, they can change perceptions and points of view, and they can adopt more constructive and effective reactions. The psychotherapy group can become a laboratory for practicing new behaviors.

Group psychotherapy is suitable for people with a large variety of problems and difficulties, from people who would like to develop their interpersonal skills to those with emotional problems such as anxiety, depression, and so forth. While support groups are developed for people in the same situation or crisis (e.g., groups for bereaved parents,

groups for sexually abused women), the prototypical psychotherapy group is as heterogeneous as possible. The leader will try to include men, women, young and old people, married, and singles when choosing people for the group in order to create a microcosm of the participants' world. As noted earlier, the likelihood that group participants will manifest their particular issues in the group makes group psychotherapy especially effective for people with interpersonal difficulties and problems in social, personal, or work relations.

## Effectiveness

Group psychotherapy is usually more cost effective than individual therapy, and possibly even more clinically effective. Evidence from studies published over the last 20 years supports the overall effectiveness of group psychotherapy, and differential effectiveness is dependent upon complex interactive variables present in group treatment.

There are many benefits of group therapy. Because of the confidential, supportive atmosphere, group members can work through personal issues themselves and help others to work through theirs, with members benefiting both through observation and active participation. The group allows members to explore their issues in a social context that mirrors real life, and it provides members with an opportunity to observe and reflect on social skills and to give and receive immediate feedback about issues, problems, and concerns affecting life.

Many professional helpers conduct psychotherapy groups: psychologists, counselors, social workers, psychiatrists, and psychiatric nurses and technicians. The best group psychotherapists are well-trained, reliable, and ethical professionals. Reputable group psychotherapists usually belong to professional associations. In the United States, for example, membership in American Psychological Association (APA), ASGW, American Group Psychotherapy Association (AGPA), and other counseling organizations suggests a professional commitment. The only two credentials that apply specifically to group therapists and assure some degree of expertise are the Certified Group Psychotherapist, or CGP, granted by the AGPA and the Diplomate in Group Psychology awarded by the American Association for Professional Psychology (ABPP). However, many psychologists, counselors, and so forth are very effective as group leaders

even though they have not attained these professional credentials.

## HAPPINESS/HARDINESS

---

Happiness can be defined as subjective well-being or as the actualization of human potential. Hardiness refers to an attitude comprised of control, commitment, and challenge that provides the courage and motivation to help a person assess and effectively deal with stressors. This entry will examine both of these constructs and the relationship between them.

### Happiness

#### **Overview**

Counseling by its very nature attempts to alleviate problems and foster happiness. In order to help clients become happier, however, counselors must first define happiness and well-being. Today, there are two prevailing perspectives on the study of happiness. In the empirically derived *hedonic* view, well-being consists of pleasure or happiness. Research that stems from this perspective typically construes happiness as subjective well-being, people's emotional and cognitive evaluations of their lives as measured by their self-reported degree of global positive affect, negative affect, and overall life satisfaction. In the theoretically derived *eudaemonic* perspective, psychological well-being is construed as the maximization or actualization of human potential. Research that stems from this perspective generally focuses on behavior and cognitions rather than feeling. A wide range of constructs such as meaning and purpose in life, values, self-acceptance, and personal goals are studied in this perspective. In order to be complete, the study of

happiness should focus on both hedonic and eudaemonic well-being. Similarly, counselors ideally should be adept at helping clients to achieve hedonic goals such as alleviating pain and increasing happiness, as well as eudaemonic goals such as increasing meaning, enhancing life skills, and promoting effective decision making and behavior.

#### **Measurement and Constituents of Happiness**

Happiness has been measured across time periods that range from daily or hourly to over the lifetime. Although short-term happiness is related to long-term happiness, there are differences between them. Short-term happiness is more changeable than long-term or *trait* happiness (which appears to be partly genetically determined); therefore, counselors are more likely to focus on clients' short-term happiness and fulfillment. Long-term happiness is relatively stable and appears to be affected by life events only for a period of about 3 months, after which it returns to its usual level for most people. General or long-term happiness appears to be partly determined by satisfaction in particular life areas such as work, yet it is also likely that a person's overall happiness level will affect his or her satisfaction in particular life areas. Since general happiness is less changeable, and since most people report relatively high overall happiness, counselors tend to promote happiness by focusing on things that are known to increase short-term or immediate happiness.

The factors that affect happiness, and the theories of happiness, may be grouped as either *bottom-up* or *top-down*. Bottom-up theories, which focus on external

and situational factors, construe subjective well-being as the product of summed pleasurable and unpleasant moments. That is, a person is thought to be happy because he or she experiences more pleasurable moments than unpleasant moments. In contrast, top-down approaches construe subjective well-being as the product of internal traits and psychological processes such as dispositions, goals, coping styles, and adaptive processes. To more fully account for individual happiness, it is important that researchers and counselors focus on internal as well as external sources of happiness, and on the quality as well as quantity of external factors such as relationships and job.

Top-down research has found that temperament and personality dimensions such as neuroticism and extraversion are important determinants of subjective well-being and psychological well-being. Neuroticism, conceptualized as emotional instability, consists of a broad range of negative emotional traits such as anxiety, irritability, sadness, moodiness, and nervous tension. Extraversion incorporates more specific traits related to activity and energy, expressiveness, dominance, sociability, surgency, and warmth. Subjective well-being has also been associated with the personality trait of conscientiousness, and particular aspects of psychological well-being have been linked to both agreeableness and openness to experience.

Although personality is important to happiness across many cultures, personality has been found to be a stronger predictor of life satisfaction in individualistic cultures (in which the focus is more on oneself than on one's group) than collectivistic cultures (in which the focus is more on the group than on oneself). Similarly, although both self-esteem and relationship harmony are important predictors of happiness across cultures, self-esteem appears to be a stronger predictor in individualistic cultures, whereas relationship harmony appears to be a stronger predictor in collectivistic cultures. Thus, when attempting to increase clients' levels of happiness, counselors should consider their cultural values.

### ***What Leads to Happiness?***

Because personality itself is difficult to change, researchers have focused on more changeable top-down characteristics that affect happiness. In this regard, cognitive factors such as broad positive beliefs, generalized self-efficacy, dispositional optimism, positive thoughts, hardiness, and constructive thinking have been proposed to help explain how personality

and environment lead to stress resistance and happiness. Other factors thought to increase happiness are quality interpersonal relationships; physical exercise; domain-specific control beliefs (e.g., beliefs in self-efficacy and competence); future outcome expectancies; setting and meeting important, intrinsic goals that are consistent with one's value system; and learning goal-relevant skills such as problem-solving techniques and social skills. For people with a tendency to experience depression or negative affect, counseling that focuses on management of negative affect and increase of positive affect also may be helpful. For example, teaching such clients to dispute habitual negative thoughts and build in daily exercise and social activities may help them to ward off depression. Assessing clients' goals and teaching clients skills that lead to setting and achieving valued goals as well as overcoming environmental or personal blocks to goals may be an especially important avenue toward happiness. Finally, teaching effective cognitive and behavioral coping skills may be vital in helping clients to overcome problems, restore equilibrium, and increase happiness. A focus on developmental and preventive counseling interventions, such as teaching clients how to structure their time, build meaningful relationships, set and pursue valued goals, and proactively cope, may be especially helpful both in reducing their stress and increasing their happiness.

## **Hardiness**

### ***Definition***

Thought to stem from rewarding childhood experiences, hardiness is theorized to be a tripartite construct composed of a sense of *control* over experienced events, a feeling of *commitment* to various life areas, and a view of life change as a *challenge*. Persons who view stressful situations as meaningful and interesting (commitment), see stressors as malleable (control), and construe difficulties as challenges defined as hardy. These three attitudes are said to provide the courage and motivation to help persons accurately assess stressors and deal with them via active coping efforts.

### ***Measurement and Limitations***

Hardiness has been measured with a variety of self-report instruments, most commonly the Personal

Views Survey, which has recently been revised and abridged. Such measures attempt to assess control, commitment, and challenge, and then combine these indexes into an overall hardiness index. However, combining indexes into a composite hardiness index has been criticized on several grounds. First, two of the measures incorporated into the original composite measure of hardiness failed to distinguish between hardy and nonhardy groups in an earlier study. Second, of the theorized hardiness subcomponents, commitment and control tend to be correlated, and challenge often has had nonsignificant or negative correlations with commitment or control. Hardiness, then, does not appear to be a unitary construct, and many researchers have recommended that its subcomponents be measured separately.

Although factor analyses of some hardiness scales have found three factors, other analyses of subscales have found only one or two factors. Finally, the common procedure of adding scores on the three dimensions into a composite hardiness score, and then using a median split to divide participants into high-hardiness and low-hardiness groups results in heterogeneous groups that may be high in one hardiness component, but low in another.

### ***Lack of Support for Key Hypotheses***

One key hardiness hypothesis is that hardiness buffers the relationship between stress and both physical and psychological symptoms. Specifically, for persons higher in hardiness, stress is theorized to have a weaker relationship to physical and psychological symptoms. However, although some studies have found theorized buffering effects (interactions between life stress and hardiness), most have not. Hardiness generally appears to directly predict mental and physical health outcomes, but this predictive ability is independent of stress and often can be accounted for by commitment or control subcomponents. Thus, it is not necessary to postulate a composite hardiness construct when results can be accounted for more simply by commitment or control beliefs.

There is also considerable evidence that scales of hardiness may inadvertently measure neuroticism. Some items included on hardiness scales appear quite similar to items of neuroticism scales, and controlling for neuroticism often eliminates the predictive ability of hardiness. Hardiness does not affect illness through physical exercise or fitness, and generally does not

predict additional variance in future well-being above the predictive ability of commitment alone.

A second key hypothesis of hardiness theory is that approach and avoidance coping mediate the relationship between hardiness and illness—that is, that persons with higher hardiness will use more approach coping and less avoidance coping, and that more use of approach coping and less use of avoidance coping will predict less illness. Most studies have failed to support these mediational pathways. Some other key hypotheses (e.g., that hardiness modifies the stress-exhaustion process directly by fostering more positive perceptions of events and by indirectly fostering social support and improving health practices) have not yet been rigorously tested.

### ***Hardiness and Counseling***

The relevance of hardiness to counseling is unknown. Most studies that have attempted to increase hardiness have failed, and one that succeeded bolstered only the control subcomponent of hardiness. In addition, no studies have examined the relevance of hardiness to counseling outcomes. One study found that college students who chose short-term counseling to resolve developmental concerns did not differ in hardiness from college students who did not choose short-term counseling. Questions about the construct validity of hardiness and whether or not hardiness can be reliably changed raise questions about the usefulness of including hardiness measures in counseling research.

## **The Relationship Between Happiness and Hardiness**

Similarly, few studies have examined the relationship between hardiness and happiness or well-being. Several “one-shot” studies and one meta-analysis have found a relationship between hardiness and measures of well-being such as happiness, subjective well-being, and life satisfaction. One study, which examined subcomponents of hardiness that accounted for the relationship between hardiness and depression/happiness, found that individuals’ confidence in their ability to handle change and/or social interactions, belief in their competence in general, and receipt of personal meaning from their social and political activities accounted for the effect. Thus, as in research on the relationship between hardiness and other constructs, it may be the subcomponents of hardiness rather than composite hardiness that is responsible for the relationship between hardiness and happiness.

It should be noted that these subcomponents are not unique to hardiness theory, and their effects may be accounted for more simply by other theories. Furthermore, in light of evidence that neuroticism accounts for many of the relationships between hardiness and outcomes, studies of the relationship between hardiness and happiness should control for neuroticism. Finally, gender differences have often been found in the relationship between hardiness and its constituents and outcomes, raising the possibility that even results that are consistent with hardiness theory do not apply to men and women. In light of these findings, studies of hardiness that include both men and women should test for differences in findings across gender.

Given weak evidence for the construct validity of hardiness and the failure to consistently confirm the central buffering and mediational hypotheses, several researchers have recommended abandonment of hardiness research. Nevertheless, study of hardiness continues. Most studies continue to utilize one-shot data collection and correlational analyses to examine the relationships between hardiness and a variety of outcomes, such as adjustment, quality of life, and grief resolution. In order to make a substantive contribution to our understanding of personality and mental health, more longitudinal studies of hardiness should be conducted. Overall, however, the construct validity of hardiness is still doubtful, and hardiness appears to be of questionable relevance to counselors.

Owen Richard Lightsey, Jr.

*Author's Note:* The above entry for happiness relies on and contains information that was first summarized by Lent (2004). The entry for hardiness contains an update of information that was first summarized by Lightsey (1996).

## HARMFUL PSYCHOLOGICAL TREATMENTS

A widely accepted credo among medical and mental health professionals, attributed to the Greek physician and “father of medicine” Hippocrates, is *Primum non nocere* (“First, do no harm”). Yet, despite the signal importance of this credo, the field of psychotherapy has displayed relatively little interest in the question of potentially harmful psychological treatments. For example, in 2006, the American Psychological Association (APA) Presidential Task Force on Evidence-Based Practice barely mentioned the problem of harmful treatments.

There is no question that psychotherapy is helpful on balance. Meta-analyses consistently demonstrate that a broad spectrum of psychotherapies, including behavior, cognitive-behavioral, interpersonal, and insight-oriented therapies, exert positive effects on a variety of psychological problems. These problems include mood disorders, anxiety disorders, insomnia, and bulimia nervosa. Nevertheless, this positive assessment of the state of the psychotherapy literature must be balanced against one sobering fact: A nontrivial number of clients become worse following psychotherapy.

## Psychotherapy Deterioration

Estimates of *psychotherapy deterioration*—that is, worsening of symptoms following psychotherapy—vary across controlled studies, but typically range from

3% to 10%. In the substance abuse literature, estimates of deterioration have often been higher, averaging 10% to 15%. These percentages have led some researchers, such as Hans Strupp, Richard Stuart, and Scott Lilienfeld, to suggest that psychotherapy can in some cases be *iatrogenic*, that is, capable of causing harm.

Moreover, comprehensive *meta-analyses* (quantitative reviews) of the psychotherapy outcome literature have been reasonably consistent in revealing that control groups—groups that do not receive treatment—show higher end-state functioning than groups that receive treatment in a nontrivial minority of studies. A classic meta-analysis of psychotherapy outcome studies by Mary Lee Smith and Gene Glass found this to be true in 9% of the scientific investigations of the efficacy of psychotherapy. Later meta-analyses have reported similar or even higher percentages of negative outcomes. Even more troubling, meta-analyses of treatments for adolescent behavioral problems have suggested that as many as 29% of studies yield negative outcomes.

Troubling as they are, reported percentages of psychotherapy deterioration and negative effect sizes from meta-analyses are difficult to interpret. As the logical error of *post hoc, ergo propter hoc* (“after this, therefore because of this”) reminds us, deterioration *following* psychotherapy is not the same as deterioration *resulting from* psychotherapy. At least some of the deterioration reported in previous studies could reflect worsening due to extratherapy variables, such as stressful life events. Moreover, certain individuals who deteriorate following psychotherapy might have been even worse off had they not received psychotherapy. Therefore, estimates of psychotherapy deterioration, although suggestive of therapy-induced harm in some cases, cannot be interpreted directly as evidence for the negative effects of therapy.

The same holds for negative effect sizes from meta-analyses. Such effect sizes, especially if close to zero, could reflect random sampling error around a mean effect of zero. As a consequence, treatments that yield small negative effects could be merely inert rather than harmful per se. It should be noted, however, that inert treatments can cause harm indirectly by leading clients to forgo more efficacious therapies. Economists refer to this side effect as an *opportunity cost*, meaning that ineffective treatments may lead consumers to forfeit opportunities for successful treatment.

Randomized controlled trials are the best means of ascertaining whether deterioration following

psychotherapy is attributable to the effects of psychotherapy. In randomized controlled trials, investigators randomly assign some clients to receive the treatment, and others to either receive no treatment or an alternative treatment. If treated groups show worse functioning than untreated control groups following psychotherapy in replicated randomized controlled trials, one can be reasonably confident that a psychological treatment is harmful.

Yet even here, the absence of mean differences between treatments can mask iatrogenic effects. For example, certain treatments may markedly increase the variance in outcomes but leave the average outcome largely or entirely unchanged. In these instances, psychotherapies have produced improvement in some clients but worsening in others. As a consequence, consumers of psychotherapy outcome research must be certain to attend not merely to differences in mean scores following treatment but to potential differences in variance.

### Harm as a Multifaceted Phenomenon

Making matters more complex, harm following psychotherapy is a multifaceted phenomenon. First, harm can be manifested in myriad forms, including a worsening of the signs and symptoms of a disorder, emergence of new signs and symptoms, excessive dependency on therapists, and reluctance to seek future treatment. Traditionally, psychotherapy outcome researchers would regard only the first two of these forms of harm as “deterioration.” In some cases, as in certain coercive restraint therapies (described below), psychological treatments may even produce serious physical harm.

Second, harm can occur in certain symptom domains (e.g., heightened anxiety) but not in others (e.g., depressed mood). This point underscores the need to assess harmful effects using multiple indicators of psychological functioning.

Third, certain treatments may be harmful primarily for the relatives of clients rather than clients themselves. As this entry will discuss below, facilitated communication for autism and recovered memory techniques appear to have led to numerous uncorroborated allegations of sexual abuse against the family members of clients.

Fourth, certain treatments that are efficacious in the long term may engender symptom worsening in the short term. For example, some effective marital therapies appear to result in time-limited increases in marital distress early in treatment, probably because

they force partners to confront long-avoided emotional conflicts.

### Potentially Harmful Therapies

Attention has only recently been accorded to the development of criteria for ascertaining whether a form of therapy is potentially harmful. In recent work, Scott Lilienfeld and his colleagues have generated a provisional list of potentially harmful therapies. Readers are advised to bear in mind that this list is preliminary. It will almost certainly be revised in coming years as additional data become available.

To qualify as a potentially harmful therapy, a treatment should be demonstrated to (a) be harmful across replicated studies (ideally randomized controlled trials), or (b) result in marked increases in adverse events shortly after the introduction of treatment, events that otherwise rarely occur (e.g., recovered memories of trauma), as reported across multiple case studies. Inclusion of a treatment on the list of potentially harmful therapies does not mean that it is harmful for all or even most clients. Instead, a treatment's being designated as potentially harmful should alert therapists to the distinct possibility that the treatment may pose harm in certain cases.

Scott Lilienfeld perused the scientific literature and compiled a list of potentially harmful therapies in 2007. This literature provides reasonably clear-cut evidence that the following six treatments—taken from Lilienfeld's more comprehensive compilation—qualify as potentially harmful therapies.

#### ***Critical Incident Stress Debriefing***

##### **The Treatment**

Critical Incident Stress Debriefing, commonly called *crisis debriefing*, is a widely used treatment designed to ward off symptoms of posttraumatic stress disorder in individuals exposed to trauma. Several thousand counselors administered crisis debriefing or variants of this treatment to the witnesses of the September 11, 2001, terrorist attacks in New York City. Crisis debriefing is typically conducted in a single group session and lasts several hours, although it is occasionally spread out across several sessions. In traditional crisis debriefing, therapists strongly encourage group members to discuss and “process” their negative emotions associated with the trauma. They outline the

symptoms of posttraumatic stress disorder that group members are likely to experience following trauma, and discourage group members from discontinuing participation once the session is underway. With respect to the lattermost point, some crisis debriefing counselors even ask group members to retrieve members who have left in mid-session.

##### **The Evidence**

A meta-analysis of randomized controlled trials for crisis debriefing yielded a small negative effect size ( $d = -.11$ ) for posttraumatic stress disorder symptoms. That figure indicates that individuals exposed to trauma who receive crisis debriefing actually end up with slightly more symptoms of posttraumatic stress disorder than individuals who receive no treatment. Moreover, the results of three randomized controlled trials indicate that crisis debriefing can be markedly harmful for at least some trauma-exposed individuals, perhaps because this procedure impedes natural recovery processes. Incidentally, at least some evidence from randomized controlled trials suggests that grief therapies, which also encourage the expression of intense negative affect following painful experiences, can be iatrogenic for individuals undergoing relatively normal grief reactions.

#### ***Scared Straight Programs***

##### **The Treatment**

Scared Straight programs became popular in the 1970s and were featured in an influential 1978 documentary on Rahway State Prison in New Jersey. The programs aim to frighten at-risk teenagers away from a life of crime by showing them the terrifying realities of prison life. Many of these programs introduce troubled adolescents to convicts in prison.

##### **The Evidence**

A meta-analysis of seven randomized controlled trials and quasi-experimental studies of Scared Straight programs revealed that they increased the chances of reoffending by 60% to 70%. The mechanisms underlying these negative effects are unknown, although some authors have suggested that Scared Straight programs may contribute to further alienation among a subgroup of already alienated teenagers. The research evidence for other “get tough” interventions

with troubled adolescents has been similarly inconclusive or negative. For example, the research support for popular “boot camp” programs for adolescent criminals is mixed. Some studies show significant positive effects, but others show significant negative effects. The factors that account for these varied outcomes are unknown. As a consequence, there is at present no way for practitioners to know whether boot camp interventions will be beneficial or harmful.

### **Facilitated Communication**

#### **The Treatment**

Facilitated communication is based on a radical theory that infantile autism and related developmental disabilities are primarily movement disorders, not mental disorders. According to facilitated communication proponents, individuals with autism suffer from *developmental apraxia* (i.e., a disorder that interferes with the child’s ability to perform well-coordinated movements, including speaking). This condition supposedly accounts for their poor or even (in severe cases) absent verbal abilities, as well as other movement difficulties. Therefore, advocates of facilitated communication argue that individuals with autism and similar disorders can purportedly generate communications using a computer keyboard or letter pad with the assistance of a trained facilitator who offers a combination of guidance and resistance to the individuals’ hands.

#### **The Evidence**

Controlled studies in which individuals with autism and their facilitator were shown different stimuli and had to type out which stimulus they saw provide overwhelming evidence for an *ideomotor effect*—a phenomenon in which the facilitator unconsciously makes subtle motions that influence the communications of autistic individuals. Specifically, in these studies the word typed was in essentially all cases the word seen by the facilitator, not the word seen by the autistic individual. Indeed, there is no compelling evidence that any facilitated communications are generated by autistic individuals themselves. Moreover, facilitated communication has been associated with at least five dozen allegations of sexual abuse against the parents and relatives of autistic children. Most of these allegations have never been corroborated by objective evidence.

### **Coercive Restraint Therapies**

#### **The Treatment**

Coercive restraint therapies are a subset of attachment therapies, which are based on the unsupported notion that certain psychological difficulties, including aggression and oppositionality, stem from aberrant early attachment experiences. These experiences include a premature or abnormally difficult birth. Coercive restraint therapies, like other attachment therapies, are intended to ameliorate these adverse experiences. They include *holding therapy*, in which therapists physically restrain children or adolescents in an effort to release suppressed rage, and *rebirthing therapy*, in which therapists attempt to engage the client in reenacting the trauma of birth. In some variants of rebirthing therapy, practitioners wrap the child in blankets to create an analogue birth canal, and they simulate the birth process by squeezing on the child repeatedly.

#### **The Evidence**

There are no controlled studies supporting the efficacy of coercive restraint therapies or other attachment therapies. Moreover, several children have been injured or suffocated to death during coercive restraint therapies—including 10-year-old Candace Newmaker, who died in Colorado in 2000 during a rebirthing session.

### **Recovered Memory Techniques**

#### **The Treatment**

Several surveys from the 1990s suggest that a sizable proportion of therapists (perhaps 25%) make regular use of suggestive techniques to unearth purportedly recovered memories of early trauma, particularly child sexual abuse. These techniques include repeated therapist prompting of memories, hypnosis (including hypnotic age regression), guided imagery, and “body work,” which encourages clients to access “bodily memories” of early abuse.

#### **The Evidence**

The question of whether suggestive techniques can ever uncover accurate memories of abuse remains scientifically controversial. Nevertheless, laboratory research leaves little doubt that these techniques can lead to *false memories* in a substantial percentage of

participants. Moreover, findings that recovered memory techniques can engender memories of alien abductions and even past-life child abuse offer *existence proofs* that at least some of the memories produced by these techniques are false.

There is also strong reason to suspect that false memories can lead to significant harmful effects in both clients and their family members. For example, data from recovered memory legal claims in Washington State indicate that suicidal ideation increased nearly sevenfold and that psychiatric hospitalizations increased nearly fivefold over the course of recovered memory treatment. Although these findings do not provide definitive evidence of causality, they raise serious concerns about the potential negative effects of such treatment. Moreover, many families have been torn apart by uncorroborated accusations of sexual abuse by children against parents.

### ***Dissociative Identity Disorder-Oriented Treatment***

#### **The Treatment**

Dissociative identity disorder-oriented (DID-oriented) treatment is designed to elicit *alter personalities* (i.e., alternate personalities or *alters*) in individuals suspected of having DID (formerly known as *multiple personality disorder*). The core premise of this treatment is that patients with DID harbor hidden identities that must be brought forth for improvement to occur. DID-oriented treatment methods include a variety of suggestive treatment techniques, including contacting supposed alters through hypnosis, introducing alters to each other, and mapping out the relations among alters. One prominent DID-oriented therapist advocates the use of a “bulletin board” to allow alters to post messages to each other. Another advocates “inner board meetings” as a method of permitting alters to communicate.

#### **The Evidence**

Multiple lines of evidence suggest that DID-oriented techniques more often create alters than uncover them, probably by treating poorly integrated aspects of patients’ personalities as though they were independent identities. For example, only about 20% of patients with dissociative identity disorder display clear-cut alters prior to treatment. Alters emerge in the

remaining 80% of patients only following DID-oriented therapy. Moreover, the number of alters tends to increase over the course of DID-oriented therapy. This finding is worrisome given that the number of alters in dissociative identity disorder patients is associated with a significantly longer time to “fusion,” that is, the integration of alters into a single personality.

### **Future Directions**

Although research evidence indicates that psychotherapy is generally helpful, a growing body of data suggests that certain psychological treatments can be harmful for certain clients and their families. The fields of counseling and clinical psychology are awakening to the need to devote additional resources to the identification of potentially harmful therapies. Efforts to (a) understand the psychological mechanisms underlying the iatrogenic effects of potentially harmful therapies, (b) find better means of detecting and preventing these effects, and (c) educate psychotherapists and mental health consumers regarding the hazards of harmful psychological treatments should therefore be accorded greater attention.

## HEPPNER, PUNCKY PAUL (1951– )

---

Puncky Paul Heppner, born on February 24, 1951, in Bismarck, North Dakota, is a counseling psychologist at the University of Missouri. Early in his career Heppner significantly advanced psychologists' understanding of the role of social influence in the counseling process. Despite the importance of this work, he is most widely known for his significant theoretical and empirical contributions to our understanding of problem-solving behavior.

Heppner received his Ph.D. in counseling psychology from the University of Nebraska at Lincoln in 1979

and accepted a position at the University of Missouri–Columbia (MU) where he remains to date. He has served as training director of the counseling psychology doctoral program and as chair of the Department of Educational, School, and Counseling Psychology. He also cofounded and codirects the University of Missouri Center for Multicultural Research, Training, and Consultation.

In the early 1980s, Heppner developed the Problem Solving Inventory, a widely used measure of applied problem solving that has been used in more than 130 empirical studies. His research on the role of problem solving with stressful life events demonstrated that across a wide range of populations, an individual's problem-solving appraisal (i.e., problem-solving self-efficacy) can moderate the harmful effects of stress. This program of research shaped the conceptualization of counseling as a process of helping people resolve their personal problems, thereby decreasing their distress and enhancing their well-being.

In 1987, Heppner advocated a change in counseling psychologists' conceptualization of problem solving. His innovative application of an information processing perspective to understanding problem-solving behavior anticipated a major paradigmatic change in the conceptualizing of problem solving. He also has been known by many graduate students as the first author of a premier research design text in the field of counseling, *Research Design in Counseling*. Heppner further shaped counseling psychology through his active involvement in professional service. He edited the Lifelines series in the *Journal of Counseling Development* from 1984 to 1990, which published biographies of pioneers, leaders, and early training institutions in the fields of counseling. He edited *The Counseling Psychologist* from 1997 to 2002. He has been involved in APA Division 17 (Society of Counseling Psychology) in a variety of roles, most notably serving as president from 2004 to 2005.

## HILL, CLARA E. (1948– )

---

Clara E. Hill, born on September 13, 1948, in Shivers, Mississippi, has contributed profoundly to counseling psychology through her innovations in counseling process and outcome research, development of models for teaching helping skills and for working with dreams, and creation of a qualitative research methodology. She has also received several of counseling psychology's highest honors.

Hill completed her undergraduate degree in psychology and her master's and doctoral degrees in counseling psychology at Southern Illinois University. She then joined the Department of Psychology at the University of Maryland, where she is now a full professor. Important early career mentors include Bill Anthony, Bruce Fretz, Paul Schauble, and John Snyder; she has mentored numerous talented protégés, including Jean Carter, Rachel Crook-Lyons, Aaron Rochlen, Barbara Thompson, and Libby Williams. Hill also has influenced counseling psychology research as editor of two of its leading journals.

Hill has contributed to counseling process and outcome research by developing innovative procedures for identifying and measuring moment-by-moment interactions between counselor and client. These innovations enable a deeper and more incisive understanding of the counseling process and its immediate effects. Hill herself applied these techniques to the examination of counselor intentions and techniques (e.g., self-disclosure, silence), client reactions and behaviors, secrets and things left unsaid, misunderstandings, client anger, and client insight.

Hill also applied the knowledge gained from process research to the development of a model for training new counselors. *Helping Skills: Facilitating Exploration, Insight, and Action*, now in its second

edition, provides an empirically grounded three-stage model (i.e., exploration, insight, action) for mastering basic counseling skills that is widely used at the undergraduate and graduate levels.

In addition, Hill developed an accessible model for working with clients' dreams. She views dreams as one avenue through which clients may reach greater understanding of their difficulties and develop strategies to address them. She integrated her helping skills model and existing dream interpretation models into a three-stage process counselors use to facilitate clients' understanding of their dreams. The process begins with an exploration of the client's major dream images. Counselor and client then use that foundation to seek insight into the meaning of the dream and to determine how clients can make changes in their waking life. In over 20 studies, Hill has helped establish that dream work is effective in facilitating insight and action ideas, and in fostering the working alliance and client satisfaction.

Finally, Hill has contributed to the development of a qualitative research methodology (i.e., consensual qualitative research, or CQR). CQR enables researchers to examine experiential phenomena: Because participants respond verbally (often via a telephone interview) to a semistructured protocol of open-ended questions, the rich data obtained using CQR enable researchers to examine phenomena in depth. A primary team of researchers works collaboratively to collect and analyze participant data, and outside auditors check the work of the primary team. CQR has been used extensively to study the counseling process.

## HOMework ASSIGNMENTS

Homework assignments are tasks that clients in counseling and psychotherapy work on between treatment sessions. Examples include having a depressed client do one rewarding activity a day, having a couple practice active listening skills between sessions, asking a Navajo client exploring career options to talk to an elder on the topic, having an anxious client practice progressive relaxation techniques, and asking clients to write down their dreams for later processing.

### Relevance

Homework is considered an important component in most behavioral, cognitive, systems, and solution-focused therapies. Practitioners of those methods assign homework with the greatest frequency, but most practitioners, regardless of theoretical perspective, employ home assignments at times. A panel of psychotherapy experts recently rated homework assignments as the intervention most likely to be used more frequently in future years. The economic pressures of managed care have helped spur the use of briefer forms of therapies, and homework has become a cost-effective way of increasing the impact of limited treatment time. Between-session activities have now been proposed by some theorists to be a common factor in the success of all brief therapies.

### Purpose and Benefits

By using the intervals between sessions, homework assignments increase the time clients spend engaging in activities designed to speed their recovery. Homework allows the generalization and transfer of in-session treatment gains through the use of in-vivo practice in natural settings. Clients doing home tasks can acquire insight and skills, and are more likely to view themselves as change agents rather than as passive recipients of therapy. Many counselors and therapists assess homework compliance in evaluating

both treatment progress and the strength of the working alliance. Successful homework is theorized to increase a client's sense of mastery, self-efficacy, and optimism about treatment success. The skill-building approach of home activities reflects the goals of positive psychology models.

## History and Research

Recommendations for assigned tasks outside the therapy hour began appearing in the literature in the 1940s and 1950s. Theoretical and empirical attention to homework activities has largely paralleled the growth in popularity of cognitive and behavioral models of counseling and psychotherapy. Reflecting the pragmatic nature of homework itself, earlier writings often focused on practitioner recommendations, and became available in published workbooks and manuals. Empirical research has demonstrated that adherence to homework assignments is one of the predictors of successful treatment outcome, and that clients who do the most homework benefit the most in treatment.

Preliminary studies suggest that homework is more often completed when tasks are specific, rehearsed in session, and matched to client strengths, motivation level, and treatment goals. Clients may comply more when they have choices of tasks, and when therapists write down the assignment and review it in the next session. Issues presently being investigated by psychologists include these and other factors influencing client compliance with assignments, the reliability of measures of homework quality and compliance, and factors in the process of assigning homework that make it most effective.

## HOPE

---

Human weaknesses such as hopelessness and aggression have often been the focus of psychologists. This attention to weakness has resulted in information on treatments of psychological disorders such as anxiety and depression. However, with the recent emergence of the positive psychology perspective, more focus is being given to studying human strengths. The aim of positive psychology is to help health care, education, and business professionals apply a science that focuses on the understanding of what makes life worth living. *Positive psychology* is an umbrella term for the study of positive character traits, positive emotions, and enabling institutions. One example of such human strength that has been studied widely is the construct of hope.

### Hope Theory

From the late 1950s and into the 1960s, several theorists focused on the concept of hope and centered the explanation of hope around a person's positive expectations for goal attainment. Simply stated, hope was viewed as the perception that one's goals can be attained. Over time and across research examining the construct, the conceptualization of hope evolved into a much more complex and diverse theory. According to Rick Snyder and his colleagues, hope is a cognitive set that is composed of *agency* (goal-directed determination) and *pathways* (planning ways to meet stated goals). These components add up to the capacity for subjective evaluation of goal-related capabilities, or hope.

The agency component of Snyder's hope theory involves the cognitive energy or willpower that allows an individual to get moving toward his or her goal. The agency component also can be defined as an individual's perceived ability to begin movement toward a goal, and to maintain that movement along the envisioned pathway until the desired goal is reached. Self-affirming statements, such as "I know I can do this" and "I will get this done," are frequently associated with the agency component. Individuals who usually

engage in this type of self-affirming self-talk are those with high levels of hope, whereas individuals who do not typically engage in this type of self-talk are those with low levels of hope.

The pathways component of Snyder's hope theory involves an individual's perceived ability to produce effective routes to reach his or her goals. In order to attain imagined goals, people must be able to perceive that they have the ability to develop possible routes to reach their goals. Individuals with high levels of hope tend to have the ability to create many possible routes to reach their goals, whereas individuals with lower levels of hope may have difficulty creating plans to reach their desired goals. Goals can be long term and/or short term, and they should be attainable by the individual. Effective goal-directed thinking requires both agency thoughts, or goal-directed energy, and pathways thoughts, or the perceived capacity to create workable routes toward goals. The Hope Scale developed by Snyder measures both the agency and pathways components of hope.

### Hope and Aspects of Well-Being

Psychological well-being involves an active engagement in the world, a sense of meaning and purpose in life, and a connection to people or objects beyond oneself. Hope theory provides researchers and practitioners with a framework for understanding and enhancing well-being and adaptive ways of functioning. The remainder of this entry discusses research that links hope to specific aspects of well-being, including academic success, physical health, psychological adjustment, and meaning in life.

### Hope and Academic Success

An important aspect of succeeding in today's society is for one to learn and perform well in educational settings. To be academically successful, students need the ability to enhance their perceived capabilities of finding multiple pathways to meet their educational goals and the motivations to pursue these goals by applying hopeful thinking. Students also need to overcome self-deprecatory thoughts and negative emotions, and to be able to stay on task through hopeful thinking.

Research shows that hope and academic achievement have a strong relationship. Hope relates to higher achievement test scores in grade school children and higher semester grade-point averages in

college students. Hope Scale scores taken at the beginning of college students' first semester predicted higher cumulative grade-point averages, higher graduation rates, and lower dropout rates. Aspects of goals, including goal commitment, goal attainability, and goal progress, play an important role in a student's academic success. The working combination of goal commitment and goal attainability accounted for significant portions of variance in self-assessment of progress toward goal achievement. Perceived progress in goal achievement acts as a cause of change in well-being. If one imagines the negative effects (i.e., lost opportunities, sense of failure, unfulfilled talents) that may occur over a lifetime for students who do not succeed in educational settings, then the research showing that hope may reduce or prevent these negative effects is crucial.

### ***Hope and Physical Health***

Hope has been positively linked to the core foci of health psychology, including promoting and maintaining good health, and preventing, detecting, and treating illness. The powers of hope have been described in terms of primary and secondary prevention. Primary prevention involves thoughts and actions that are intended to reduce or eliminate the chances that subsequent health problems, either physical or psychological, will occur in the future. Secondary prevention involves thoughts and actions that are directed at eliminating, reducing, or containing a problem once it has occurred.

Research concerning hope and the primary prevention of physical illness has revealed that people with higher levels of hope use information about physical illness to their advantage to do more of what helps and less of what is harmful. Knowledge is used as a pathway for prevention. Snyder and colleagues discussed that women with higher levels of hope performed better on a cancer facts test than women with lower levels of hope, even after controlling for their past academic performances and their contacts with others who have had cancer. Furthermore, women with higher levels of hope reported higher intentions to engage in cancer prevention activities than women with lower levels of hope, and people with high hope reported engaging in more preventive behaviors, such as physical exercise, as compared to people with low hope.

Hope also plays a very important role even after physical illness develops. Hope should facilitate one's coping with the pain, disability, and other stressors of

physical illness, and research shows that hope has been related to better adjustment in conditions involving handicaps, severe injury, and chronic illness. More specific studies have shown that higher levels of hope have related benefits in dealing with burn injuries, spinal cord injuries, severe arthritis, fibromyalgia, and blindness.

People with lower levels of hope often experience higher anxiety when it comes to physical illness, and this may result in maladaptive avoidance coping. It also has been shown that people who are physically ill and who have low hope can be overtaken by self-focus and self-pity which, in turn, increases anxiety and compromises the healing process. However, once ill, people with high hope appear to remain appropriately energized and focused on what they need to do to recuperate. It is believed that people who are experiencing profound or chronic pain and who have higher levels of hope should be able to lessen their pain by enlisting more strategies, or pathways, and by having a higher likelihood of using those strategies, or agency, than those with lower levels of hope. Research clearly shows that hope theory can be usefully applied when it comes to prevention, detection, and effective coping with physical illness.

### ***Hope and Psychological Adjustment***

Psychological adjustment is another aspect of well-being that is influenced by hope in many ways. Specifically, hope is related positively with positive affect and negatively with negative affect. It also has been shown that manipulations to increase hope levels resulted in increases in positive affect and decreases in negative affect, and people who have higher levels of hope report having more positive and fewer negative thoughts every day. One specific study showed that college students with high hope as compared to students with low hope reported feeling more inspired, energized, confident, and challenged by their goals, as well as having elevated feelings of self-worth and low levels of depression.

As stated previously, hope is critical for physical health. Hope also is critical for psychological health. Hopeful thought involves assets, such as the ability to establish clear goals, imagine workable pathways to those goals, and motivate oneself to work toward those goals, and people with higher hope yield more successful goal pursuits in many different areas. A stressor is something that interferes with one's

normal ongoing goal of being happy. When one is confronted with a stressor, one must find alternative paths to obtain the “normalcy” goal. People with higher hope are able to produce more strategies for dealing with the stressor and express a greater likelihood of using those strategies, as well as find benefits in ongoing dealings with stressors. Dealing with stressors in one’s life, either effectively or ineffectively, is something that influences one’s feelings, emotions, and affect.

It is argued that positive emotions should flow from perceptions of successful goal pursuits and negative emotions are the product of unsuccessful goal pursuits. Research has shown that when people are confronted with insurmountable goal blockages, they experience negative emotions, and when people are able to follow successful, unimpeded goal pursuit after overcoming impediments, they experience positive emotions. It also has been reported that people who encounter severe difficulties in pursuit of important goals report lessened well-being, and the perceived lack of progress toward major goals is the cause of reductions in well-being. The opposite is true, as well. It has been reported that successful pursuit of goals is associated with elevated self-esteem and well-being.

Snyder and colleagues discussed that psychological health is related to people’s routine anticipation of their future well-being. People with higher levels of hope should expect more positive levels of psychological health as compared to people with lower levels of hope. These kinds of positive expectations will produce higher confidence, and those with high hope will perceive that their hopeful thinking will protect them against future stressors.

Psychological health also involves thoughts and actions that eliminate, reduce, or contain a problem that has already presented itself. When people with high hope encounter a goal blockage, they are flexible enough to be able to find alternative goals and alternative ways to meet these goals, whereas people with low hope tend to ruminate unproductively about being stuck. People with high levels of hope tend to have friends with whom they share a strong sense of mutuality. When stressful situations arise, those with high hope can call on these friends for support. However, people with low levels of hope tend to be lonelier, and lack friends with whom they can talk and call upon in stressful times. All of this plays into people’s overall psychological adjustment.

## Hope and Meaning in Life

Life meaning has been one of the most elusive concepts in many fields of research and study. There are many theories discussing what life meaning truly is, but generally, conceptualizations of meaning share at least two notions. First, life meaning is a global way of assessing or understanding one’s life, and second, believing that life is meaningful is associated with lower levels of negative emotions (i.e., depression and anxiety) and lower risk of mental illness.

Snyder and colleagues posited that hope should relate strongly with life meaning, as measured by a number of instruments assessing meaning or purpose in life, because it is through individuals’ self-reflection about the goals they have selected and the progress they perceive in their journey toward these goals that individuals construct meaning in their lives. Hope Scale scores were found to have significant positive correlations with the life meaning measures, suggesting that hope theory offers a new way to look at the nature of meaning.

Life meaning is viewed as a wider concept than hope because no life meaning theory can be reduced simply to goal pursuit. However, hope can be conceptualized as a component of life meaning, central to its ability to predict variables of well-being. Studies have demonstrated that relations between hope and depression are moderated by life meaning. Researchers believe that the perceived ability to achieve goals that is associated with having higher hope works as a buffer against depression and anxiety, and this, in turn, is related to higher well-being and higher life meaning.

## HUMANISTIC APPROACHES

---

Humanistic approaches to counseling include a number of theoretical viewpoints. The dominant perspectives in this category are person-centered therapy and Gestalt therapy, which emerged in the 1950s and 1960s as alternatives to the prevailing approaches of the time,

psychoanalysis and behaviorism. This entry will review person-centered therapy and Gestalt therapy, along with a more recent approach that combines elements of these two: process-experiential psychotherapy.

### Assumptions of Humanistic Approaches

Humanistic theorists emphasize the freedom and responsibility of the individual. In psychology, these theoretical viewpoints evolved as a reaction to psychoanalytic and behavioral perspectives that characterized human behavior as determined by forces not directly under individual control. The humanists rebelled against the conception of humans as pawns controlled by genetically programmed instinct or environmental forces and accompanying assumptions that seemed to split the individual into pieces. Instead, humanistic theorists emphasize individual agency and holistic functioning.

A related assumption in humanistic approaches is the importance of individual experiencing. Human functioning is viewed as the direct result of the internal world of the individual; thoughts and feelings are given primacy over external forces in the motivation and production of behavior. However, an essential element of human experience is the relationship with the surrounding environment, most notably, other individuals.

Humanistic approaches to counseling tend to emphasize self-awareness, and these therapists prompt clients to explore their inner worlds. In these systems, it is recognized that it is natural for individuals to deny or distort aspects of experience that they find painful or unacceptable to their self-conceptions. These denied or distorted experiences cause problems in living. The tendency to reject aspects of life experience is seen as learned, primarily from the cultural norms and expectations that are incorporated into people's self-concepts as they traverse the developmental path from childhood to adulthood. Freed from societal influences, individuals' natural growth tendencies lead them to become fully functioning, healthy (in both mind and body) human beings who can adequately satisfy their physiological and psychological needs. Healthy individuals freely experience internal and external events and processes, and live authentic lives unfettered by the rules and dictates of society.

Although specifics differ somewhat across theories, one important task of the therapist in humanistic approaches is to provide the correct therapeutic

environment for the client. The client must be freed from blocks in experiencing so that they can become authentic. To do this, the therapist, too, must be authentic. The therapeutic relationship is viewed as an encounter between two individuals; the client's experiencing is blocked in some way, and the therapist is experiencing more freely. Ultimately, the therapist's acceptance of the client leads to the client's acceptance of the self, with all of its experience.

### Person-Centered Therapy

Person-centered (PC) therapy was developed by Carl Ransom Rogers and has been known by three different names. It was called *nondirective* therapy when first introduced in the 1940s, and then Rogers renamed it *client-centered* therapy in the 1950s. In the 1980s, because many PC concepts were being applied beyond counseling and psychotherapy, in areas such as education, industry, and conflict resolution, Rogers began using the name *person-centered* approach to reflect the potential for application of this theory beyond traditional individual psychotherapy.

As noted earlier, PC theory was developed by Rogers in response to the two dominant psychotherapy approaches in the 1940s and 1950s: Freudian psychoanalytic theory and behavior therapy. Rogers was one of the major figures using the humanistic approach in his time. Reflecting his positive viewpoint on human nature and his insistence on equality in the counseling relationship, he was the first person to use the term *clients* (instead of *patients*) to refer to individuals who seek psychotherapy.

Rogers's most prominent philosophical assumption was that human beings are inherently good. Rogers believed that the primary motivation of human behavior is to grow into one's full capacity. Humans have a self-actualizing tendency that will orient people toward growth if unconditional positive regard and emotional support are provided. When individuals are well functioning, this growth is guided by the internal regulation of the organismic valuing process. The *organismic valuing process* evaluates experiences in terms of whether they are good or bad for the organism, without reference to cultural or societal standards. In addition, Rogers thought that all human beings have a need for positive regard and that individuals seek love from significant others to fulfill this need.

The concept of the self occupies a central position in PC theory. As individuals grow and experience the

world, they soon learn to differentiate self from others and develop a sense of who they are. All of the experiences related to the self and perceptions about who the self is, as well as the values (e.g., positive or negative) associated with them, comprise an individual's *self-concept*. On the other hand, the concept of *ideal self* refers to what a person would like to be based on societal messages. In psychologically healthy individuals, the ideal and real selves are nearly identical.

Rogers used the term *conditions of worth* to describe the underlying source of humans' problematic behaviors. When individuals are young, if they consistently perceive that they are more valued or liked by significant others when they perform some behaviors and less valued when they perform others, then they experience conditions of worth. Initially, conditions of worth are external; that is, they are the reactions of others (such as parents) who value behaviors differentially, often based on societal norms (e.g., boys don't cry, girls don't shout). However, because the need for love from significant others is so intense, the conditions of worth will be internalized as parts of the self if they continue to exist for a period of time.

When conditions of worth are internalized, the individual is said to be in a state of incongruence. Self-relevant experiences are evaluated based on whether they are consistent with the internalized conditions of worth, instead of through the organismic valuing process, which determines whether experiences are growth producing or detrimental to the organism. *Incongruence* is a discrepancy between self and experience; that is, people deny or distort some of their experiences that do not fit the conditions of worth. Another way to describe dysfunction is that the person's real and ideal self (which incorporates the conditions of worth) are discrepant.

Rogers saw therapy as an encounter between two individuals and contended that the therapist's attitude or philosophy was critical to the success of therapy. Thus, there are no formally recognized techniques in this approach. PC counselors strive to develop understanding, supportive, and empathic counseling relationships with their clients. Rogers believed that the therapist's *congruence* (or *genuineness*) was critical to the success of therapy, and along with *empathy* and *unconditional positive regard*, necessary and sufficient for client change. When the therapist consistently provides these conditions and trusts the client to lead the way, the client will be able to get beyond the

internalized conditions of worth, progressing from a state of incongruence to one of congruence. The self-actualization tendency (in tandem with the organismic valuing process) is in charge and orients the individual toward positive growth once again.

Rogers's assumption that each person has sufficient internal resources and strengths to grow and become a better person leads to a therapeutic relationship that stresses client autonomy and encourages clients to be self-directing. The main function of the PC counselor is to provide a safe, empathic, and supportive therapeutic environment that allows clients to follow their own directions. This respect for the individual's autonomy leads to PC counselors' attitude of equality within the therapeutic interaction; they eschew an expert role in the counseling process. In addition, the PC approach is phenomenological; an individual's subjective perception is considered the defining force of reality for that person. Therefore, the focus of PC counseling is on the clients and their perceptions of the situations, not what might be viewed as "reality" by others. As PC counselors respond with empathic reflection and genuine reactions to the clients' presenting concerns, they focus the clients' attention to their own internal wisdom and assist their clients' emerging self-awareness. Simultaneously, they also accept their clients as worthy and valuable beings regardless of their actions. This valuing from the therapists sets the stage for the clients' own self-acceptance.

PC theory has been criticized for being too simplistic and oblivious to the true qualities of human nature. Although counseling outcome research appears to support the effectiveness of the PC theory, empirical evidence indicates that the core conditions (i.e., counselor's empathy, congruence, and unconditional positive regard) are likely to be necessary but not sufficient for therapeutic change. However, research clearly demonstrates that the therapeutic relationship is critical to the outcomes of therapy of all kinds.

Because PC therapy focuses on the person and stresses the necessity of self-actualizing tendency for the person's healthy functioning, the individualistic emphasis within PC theory can be detrimental to clients from more collectivistic cultural backgrounds or to those who have experienced oppression. In addition, PC theory has been criticized for its lack of attention to familial and cultural factors, which may be particularly problematic in dealing with clients from other cultures. On the other hand, PC theory's trust in

the individual to know what is needed can be helpful in working with clients from diverse backgrounds.

## Gestalt Therapy

Fritz Perls is considered the founder of Gestalt therapy (GT). However, several individuals, including his wife, Laura Perls, and Paul Goodman, also made significant contributions to the development of the GT in its early stages. After Perls's death in 1970, second- and third-generation GT therapists such as Walter Kempler, Erving Polster, and Gary Yontef continued to practice and promote the approach. Over time, the theory evolved into several different versions. In fact, a somewhat confusing feature about the GT approach is that although some core principles and theoretical concepts are shared by the various versions of GT, there is little orthodox doctrine about how these are put into action.

Perls believed that humans have the potential to act and function in an authentic and holistic way. GT theory posits that all human beings have an innate tendency to grow toward fulfillment and actualization. GT's existentialist flavor is seen in its strong emphasis on an individual's choice and responsibility. Influenced by the concept of wholeness in Gestalt psychology, a branch of perceptual psychology that explores how humans create meaning out of perceptual stimuli, GT theory holds that it is human nature to integrate one's inner experiences (e.g., feelings, needs, and perceptions) with one's outer reality (e.g., environment) into a whole. According to this holistic perspective, individuals cannot be separated from their environments, nor can they be divided into parts (such as body and mind). Physical and psychological functions are inherently related; thoughts, feelings, and physical sensations are all a part of a unified being.

*Need satisfaction, contact, and awareness* are three central constructs of the GT theory. Perls believed that individuals strive to meet needs such as physical and emotional support throughout the life process. Needs are met through contact with the external environment (including other human beings) or aspects of the self. Contact is essentially an unending cycle of need emergence, activity by the individual aimed at satisfying the need, need satisfaction, and disappearance of the need. For example, when people realize they are thirsty, they might get some water and drink until their thirst is quenched. However, if they are unable to find anything to drink, their thirst is not satisfied and may intensify so

that it becomes all consuming. Psychological needs arise and are satisfied in a similar manner. Effective contact, which involves the successful completion of the cycle, leads to awareness and creates growth. Perls postulated that people have problems because they anticipate that some of their needs or parts of their selves are unacceptable to significant others or society, so they avoid contact by using defense mechanisms such as *introjection* (i.e., unquestioning internalization of values, rules, and standards of behavior from significant persons or aspects of the environment), *projection* (i.e., disowning personal qualities by seeing them as existing outside oneself, often in others who are emotionally important to the person), *deflection* (i.e., directing an impulse toward a substitute object or subject in the environment instead of the object or subject that caused the impulse), *retroflexion* (i.e., doing to yourself what you would like to do to a subject in the environment), and *confluence* (i.e., failure to establish personal boundaries, so it is not clear where you leave off and significant others in the environment begin). Since people's needs are met through contact with the environment, their needs go unmet when they use defense mechanisms to avoid contact. This disrupts their awareness of the environment and results in unfinished developmental business. Lack of awareness disrupts the ongoing cycle of contact by which people meet their needs and it contributes to further dysfunction.

The main goals of GT are to facilitate awareness, rather than directly addressing behavioral problems, and to help clients accept the ownership of their experience as well as personal responsibility for their thoughts, feelings, and behaviors. GT counselors support and encourage clients to freely experience and express their inner feelings and their needs. GT therapists often employ experiential techniques or activities in counseling to help facilitate awareness. In fact, the GT approach is often perceived as synonymous with one well-known technique called the *empty chair* dialogue. In this technique, important others are placed metaphorically in a chair and the client engages in discussions with these people. In another variant of this technique, called the *top dog/underdog* dialogue, a critical, parental facet of the self is placed in the empty chair and the therapist encourages the client's weaker, responsibility-evading self to dialogue with the tyrant. By engaging in some sort of experimentation in which clients are directed to focus on how they are feeling and what they are experiencing in the here and now, it is believed that clients will assume effective contact, heighten their awareness, and begin to accept and take responsibility for experience.

The original GT style presented by Perls was rather confrontive and directive. This was due, in part, to Perls's personal style, which some therapists imitated. However, the modern GT approach has turned its emphasis to creating an authentic, here-and-now relationship between the therapist and client. Exploring experience, however, is still the critical focus of therapy. GT therapists usually do not use any formal assessment or diagnosis. A GT counselor is to be authentic in providing feedback to his or her clients and will self-disclose if it is believed helpful.

GT has been criticized for its extreme emphasis on individual responsibility. This orientation may lead to problems in using this approach with individuals who are from cultures that are more relationship or group oriented. In addition, the emphasis in GT on verbal, emotional, and behavioral expressiveness is counter to the values of many cultural groups. However, GT's emphases on awareness, personal power, and responsibility may be encouraging and helpful to female clients in finding their worth from within rather than in others' perceptions of them.

### Process-Experiential Psychotherapy

A recent approach, process-experiential psychotherapy (PE), fuses aspects of the person-centered and Gestalt approaches. Classified by its authors as one type of emotion-focused therapy, PE is based on the assumption that human emotions are adaptive signals that tell people what is important and prepare them for action. Dysfunction results from problems in symbolizing experience, and accompanying distorted emotional processing of the experience. Thus, the goal of therapy in this approach is to help clients learn new ways of processing emotion that lead to different meanings and more adaptive coping strategies. The therapist in PE first strives to create a therapeutic climate similar to that in person-centered theory in order to evoke and understand client emotional experience. Once the relationship is established, the therapist can then use interventions that help reprocess the emotions; among these are chair dialogues similar to those used in Gestalt therapy.

Process-experiential psychotherapy emphasizes the importance of a collaborative therapy relationship and the power of the therapist's empathic prizing of the client in creating a situation in which clients can productively explore their experiences. Techniques in PE include some that are similar in person-centered theory (focusing, systematic evocative unfolding,

narrative retelling, and meaning creation) and dialogues reminiscent of Gestalt therapy's two-chair and empty-chair techniques. Focusing, systematic evocative unfolding, narrative retelling, and meaning creation are all interventions that support clients' exploration of feelings and the transformation of these feelings in ways that promote effective client responses to them. In the two-chair dialogue, clients experience aspects of themselves as they shift between two chairs. Two types of dialogues are identified: those between conflicting aspects of the self and those between the experiencing self and an aspect of the self that is blocking the expression of emotions or needs. Resolution of the conflict generally requires the two aspects to be accepted by the client so that they can work together.

## INDIVIDUAL THERAPY

---

The foundation on which individual therapy is based is the natural network of human social relationships. Discussions of personal life and personal concerns occur continually between family and friend dyads. Primary dyads for personal discussions include mother and daughter, sisters, husband and wife, mother and son, and friends. These universal networks of two people form a foundation for the value, structure, and form of individual therapy.

Within the context of individual therapy, the therapist facilitates, with the client, an exploration of what the client brings to the therapeutic setting. Thus the client is able to receive feedback from someone with a professional viewpoint. A trained counselor is unique in contrast to a friend, as he or she is emotionally present for but not engulfed in the person's life or difficulties. As in other forms of therapy, in individual therapy, a therapist's role includes reflection, active listening, giving feedback, listening with the "third ear," and modeling positive behaviors.

Many contemporary therapists identify themselves as adopting an integrated/eclectic theoretical approach rather than practicing within one single theoretical frame. Though approaches to therapy vary greatly among practitioners, therapists are generally accepting, genuine, and trustworthy.

The opportunity for undivided attention—for listening and processing to be focused just on the individual client—is a relatively unique feature of individual therapy. Total attention to the growth and development of one person gives individual therapy

its popularity and contributes to its efficacy. The therapy process, operating like a greenhouse effect, magnifies the individual's concerns and needs, illuminates the individual's self-concept, and allows a person to focus on the modification of aspects of the self that are creating problems and limitations.

### Logistics of Individual Therapy

Individual therapy occurs in many settings, including college counseling centers, community counseling centers, hospitals, prisons, K–12 schools, and private practice. The fee for individual therapy depends on the setting. In schools, colleges, the military, county clinics, and nonprofit centers, clients may receive free service. In private settings and HMO clinics, health insurance is used. Occasionally, people pay "out of pocket."

Professionals who provide individual therapy include psychiatrists, certified counselors, licensed psychologists, licensed family and marriage therapists, and licensed social workers. Some individuals seek individual therapy for clinical conditions such as depression, anxiety, anger, eating disorders, psychotic disorders, and substance-related disorders. Others seek assistance in dealing with life changes or transitions that exceed their coping resources, such as divorce, self-esteem issues, and work issues. In these instances, individual counseling is analogous to having one's own educational consultant or emotional development coach.

Sigmund Freud, the founder of psychoanalytic theory, laid the theoretical foundation for individual therapy. Successors proposed other significant theories (e.g., psychodynamic theory, person-centered theory,

existential theory, cognitive-behavioral theory, and Gestalt theory) that today provide a rich and multifaceted theoretical framework for individual therapy.

### Individual Therapy in Contrast to Other Forms of Therapy

Neither group nor couples counseling permits an in-depth exploration with the focus solely on one person. For example, in couple therapy, the therapist's attention is primarily on the space between the two partners, and in a group setting, the attention is often on the group process and the sharing of time among members. While the individual focus is appealing in a time-starved and attention-starved world, sometimes it is more intense than desired. The focus is on the client's life and is not diluted by the relationship with other clients. The structure of individual therapy makes it difficult for clients to avoid facing difficult problems.

Individual therapy may be a particularly apt choice when the topics discussed are intensely personal or traumatic for the individual. Individual therapy provides maximum privacy, so as therapy progresses and clients come to know the therapist as an accepting, understanding, and trustworthy confidant, they become less likely to manage their image and less likely to conceal critical information.

### Goals of Therapy

Clients are able to assert their own personal hopes and therapy goals during individual therapy. Individual therapy offers the opportunity for the client to work on external relationships from his or her own viewpoint, with input from the therapist. This allows the client to focus on the changes *he* or *she* would like to make that can affect his or her outside relationships.

In many ways, the therapeutic process is collaborative, as two people work together to identify hopes and goals for the therapy process. Individual counseling is a place where clients can practice new skills or behaviors through role-playing, cognitive changes, and emotion management. Evidence gleaned from half a century of research demonstrates convincingly that the outcome of therapy depends less on theory than on other common factors such as the therapeutic relationship, how much clients believe they will benefit from therapy (i.e., expectancy of therapy), and environmental factors.

### Mechanisms That Produce Change

The therapeutic relationship, or *working alliance* is of the utmost importance in most schools of therapeutic thought. The working alliance is an emotional bond between therapist and client that forms as they work collaboratively to achieve an agreement on the goals of therapy, and tasks will be undertaken to achieve those goals. The formation of a strong working alliance greatly increases the likelihood of a successful therapeutic outcome.

### Attitudes Toward Individual Therapy

In highly individualistic cultures, individual therapy is a modality that fits with the culture because the client is responsible for his or her own decisions, achievements, and losses. The losses—achievement failures, personal betrayals, geographic moves, job changes, changes in friendships—are especially difficult because they are often conceptualized in an individual culture as the individual's responsibility. Thus, therapy is a healing process, and is a way to overcome loss. In an individual, achievement-oriented culture, it is important to learn how to manage failure and loss and continue to try and to compete.

Using individual therapy as a way to improve the quality of one's life and to live effectively, as well as to lessen the distress caused by emotions such as anxiety, depression, and anger, is perceived positively by some culture groups. It is still stigmatized by other groups, in which individuals who seek the assistance of a therapist are perceived as "being crazy" or "insane."

Individual therapy can be an excellent means to achieve more personal maturity and to manage the many demands of contemporary human life. Through listening, goal setting, practice, and the like, individual therapy is a medium that can inspire change and growth at the personal level.

## INFORMED CONSENT

---

Informed consent in counseling and psychotherapy refers to the process by which clients or prospective clients receive information about the proposed treatment and subsequently decide whether to provide consent for the counselor or therapist to proceed with the treatment. Historically, informed consent requirements were applied to surgery and other medical procedures; later these requirements were expanded to include counseling and related activities. Currently, informed consent is mandated by the ethical codes that govern most counselors and psychotherapists. There is significant variability, however, in the beliefs and practices of professionals regarding informed consent, including its content, timing, method, and effect.

## Content of Informed Consent Procedures

What information should counselors and psychotherapists include during the informed consent process? Ethical codes and legal regulations typically offer little guidance regarding the specific topics to cover or particular details to address. In the absence of unambiguous guidelines, counselors and psychotherapists have developed and employed a wide variety of approaches to informed consent.

A number of topics have traditionally been included in the informed consent process. Prospective clients are generally informed about the nature of the counseling or therapy being proposed. This includes what the therapeutic approach is called, how it usually works, what activities it may involve, and how long it may last. They are also typically informed about the effectiveness of the proposed treatment, as well as potential risks and alternative treatments. Of course, the pragmatics of the treatment arrangement are also usually covered: how appointments are scheduled, where and how often sessions will take place, payment arrangements and responsibilities, and emergency contact information. Finally, informed consent procedures have customarily included confidentiality policies, including situations in which the counselor or therapist may need to break confidentiality without the permission of the client (e.g., when the therapist becomes aware of a legal duty to warn a third party of potential danger).

In addition to these essentials, a number of additional topics may merit inclusion in the present-day informed consent process. Recently, numerous authors have identified contemporary issues in the counseling or therapy field about which the client may have a right to be informed. For example, the increasing involvement of insurance companies, managed care organizations, and other third-party payers has had a widespread and well-documented influence on the counseling and psychotherapy professions, and some members of these professions believe this topic merits inclusion in their informed consent procedures. Similarly, therapy manuals (or empirically supported therapies, or best practices guidelines) have resulted in many clients in recent years receiving treatment that is to some extent predetermined or preplanned according to a diagnostic category or presenting problem. Informing prospective clients about their use by a counselor or therapist may be another relatively new addition to the informed consent procedure.

## Timing of Informed Consent

When should counselors and therapists obtain informed consent? Ethical codes and legal regulations generally suggest that informed consent be obtained as early as possible in the therapeutic relationship. The rationale behind this suggestion is clear: Clients should have the opportunity to choose whether to proceed with counseling or therapy before finding themselves immersed in it. However, counseling and psychotherapy are fundamentally different from other practices that utilize informed consent procedures. Consider, for example, a physician who obtains informed consent from potential patients facing the same medical procedure. The procedure is assumed to be essentially similar for all patients, and to be a one-time event, so the physician can provide a uniform informed consent document to all potential patients at the outset.

Counseling and psychotherapy are unique in two important ways: They unfold gradually over time in ways that cannot always be accurately predicted at the outset, and they necessarily differ from client to client. For these reasons, a standardized informed consent procedure cannot be offered to all clients at the outset. Of course, some basic information can and should be provided at the very beginning, including confidentiality and payment policies. However, discussion about more substantive issues, such as treatment orientation, duration, goals, and activities may need to be delayed until the therapist has learned enough about the client to provide personalized information. Thus, many authors on informed consent promote a “process” model rather than an “event” model, such that informed consent represents not a distinct occurrence, but an ongoing and recurrent element of counseling and psychotherapy.

Whether informed consent is viewed as a process or an event, at times it may need to be delayed as a result of client variables. If the client is in an acute crisis state or is temporarily unable to adequately comprehend the information to be provided, it may be clinically and professionally wise to delay informed consent until a more appropriate point in time.

## Methods of Obtaining Informed Consent

How should counselors and psychotherapists go about obtaining informed consent? Historically, two methods—written and oral—have been utilized.

Written informed consent procedures feature the advantage of enabling clients to read over information at their own pace, as well as the opportunity for the counselor or therapist to keep a hard copy of a signed form in the file as proof that informed consent was obtained. Oral informed consent procedures allow for more flexibility and customization of information for particular clients. They also facilitate discussion between the client and the counselor or psychotherapist.

In practice, a combination of written and oral informed consent procedures may be ideal. Numerous standardized written informed consent forms have been made available, and they can be adapted by counselors or psychotherapists working in particular contexts or with particular types of clients. However, these forms, or others originally designed by counselors or therapists for their own practices, should not stand alone. Instead, clients should be given the opportunity to ask questions during the informed consent process, and the counselor or psychotherapist should provide answers to the fullest extent possible. Counselors and psychotherapists can combine the written and oral approaches by supplementing a standard information form with a written list of questions that clients may choose to ask. Whether written, oral, or both, the method by which counselors and psychotherapists obtain informed consent should be consistent with professional ethical codes, applicable laws, and the Health Insurance Portability and Accountability Act (HIPAA).

## Effects of Informed Consent

Research by Mitchell Handelsman and others suggests that as a rule, the informed consent process has a positive effect on clients and prospective clients. Rather than perceiving the process as unnecessary or excessive, clients who are provided with readable, personalized information—as well as a chance to discuss this information—generally look favorably upon the informed consent procedure and the counselors and therapists who provide it. At its best, the informed consent procedure can facilitate not only an informed decision by the client, but a strong therapeutic alliance in which the counselor’s or therapist’s acknowledgment of the client’s autonomy is an important component.

It is also important to note that the informed consent procedure offers professional benefits to the counselor or therapist as well as the client. By appropriately obtaining and documenting informed consent,

the counselor or therapist precludes ethical violations or legal liability that may otherwise arise.

## INTEGRATIVE/ECLECTIC THERAPY

---

Eclecticism, or integration, is now the most common theoretical orientation among counselors and psychotherapists in the United States. This has not always been the case. In the mid-20th century, three dominant theories of counseling and psychotherapy were often viewed as distinct and incompatible: psychoanalysis, behaviorism, and humanism. Less contradictory forms of therapy evolved during the second half of the century, and counselors began to combine strategies from diverse theories in an eclectic manner. Early eclecticism was often criticized for its lack of an underlying theory and the absence of

formal guidelines to help counselors make decisions. In response, more formal models of integrative psychotherapy were developed, and today four general routes to integration are recognized: (1) common factors, (2) technical eclecticism, (3) theoretical integration, and (4) assimilative integration. In this entry, formal models of integration are described that exemplify each of these general routes.

### Common Factors

The *common factors* route to integration identifies core ingredients that most forms of psychotherapy share. The advantage of common factors is the emphasis on therapeutic actions that have been demonstrated to be effective. The disadvantage is that common factors may overlook specific techniques that have been developed within particular theories.

Jerome Frank and Julia Frank analyzed cross-cultural approaches to healing and identified the following common factors: (1) an emotionally charged, confiding relationship with a helping person; (2) a healing setting; (3) a rational, conceptual scheme, or myth that provides a plausible explanation for the client's symptoms; and (4) a ritual or procedure that requires the active participation of client and therapist and that both believe to be the means of restoring the client's health. The analysis concluded that the active ingredients in psychotherapy are not unique or new but have been used by healers around the world for many centuries. Research has demonstrated the importance of the therapeutic alliance as well as other common factors.

Scott Miller and his colleagues have described a contemporary common factors approach that ensures that clients experience the kind of changes they desire. This approach is based on research demonstrating common factors related to the client's role in extratherapeutic change, the therapeutic relationship, and expectancies for change. Miller emphasized the importance of working within the *client's* frame of reference as the defining "theory" for psychotherapy, in order to support active participation in shared goals. The therapeutic alliance is strengthened when counselor and client come to a consensus on the methods of treatment and share an emotional bond. There is also ongoing attention to the client's experience of the therapeutic relationship and active attempts to address problems in the relationship when they arise.

## Technical Eclecticism

Technical eclecticism is designed to improve the therapist's ability to select the best treatment for the person and the problem. This route to integration is guided by empirical data on the efficacy of different methods. The advantage of technical eclecticism is that it encourages the use of diverse strategies without being hindered by theoretical differences. A disadvantage is the lack of a clear conceptual framework describing how techniques drawn from divergent theories fit together.

The most well-known model of technical eclectic psychotherapy is Arnold Lazarus's *multimodal therapy*. This approach begins with a thorough assessment of seven modalities: behavior, affect, sensation, imagery, cognition, interpersonal relationships, and drugs/biology. Multimodal therapy represents an ongoing attempt to adapt therapy to the individual. The form and style of therapy are adapted to each client's particular needs.

Larry Beutler's model of *systematic treatment selection* represents another model of technical eclecticism. His approach uses research-based conclusions to describe principles of treatment and to identify the best interventions for particular clients. Clients are assessed on variables such as coping style, resistance level, and emotional arousal. Therapists choose a treatment focus and specific strategies that are consistent with these client characteristics. For example, psychotherapy strategies that focus on symptoms or skill building, structured problem solving, correcting dysfunctional thought patterns, homework assignments, and relaxation training may work best with clients with an externalizing coping style. In contrast, clients who use an internalizing coping style benefit most from strategies that emphasize insight and awareness, such as identifying interpersonal themes and following client affect.

## Theoretical Integration

In theoretical integration, two or more therapies are integrated to create an approach that is better than the constituent therapies. Some models of theoretical integration focus on combining and synthesizing a small number of theories at a deep level. Other models combine elements from several systems of psychotherapy at a more superficial level.

Paul Wachtel's *cyclical psychodynamics* integrates psychodynamic, behavioral, and family systems theories. These systems are seen as complementary

because psychodynamic theories focus on internal change and behavioral theories focus on the external environment. The family system is seen as a crucial environment that often reinforces interpersonal patterns. Wachtel's approach to integration depends on dynamic insight and behavioral action to recognize and change vicious cycles that are often shaped by early family experiences but maintained by current behavior.

Anthony Ryle's *cognitive analytic therapy* integrates ideas from psychoanalytic object-relations theory and cognitive psychotherapy. This approach is based on a cognitive description of relational patterns and describes target problems that often include maladaptive patterns. This reformulation is used as an ongoing reference point to help clients recognize and modify problematic patterns. Ryle encourages the use of cognitive-behavioral methods and an examination of the therapy relationship to understand the way clients enact reciprocal role patterns.

James Prochaska and Carlos DiClemente's *trans-theoretical approach* describes the relationship among several theories. This approach assumes that many systems of psychotherapy are complementary and that different theories tend to target different stages and levels of change. Prochaska and DiClemente used five stages of change (precontemplation, contemplation, preparation, action, or maintenance) and five levels of change (symptom/situational problems, maladaptive cognitions, current interpersonal conflicts, family systems conflicts, or intrapersonal conflicts) to create a two-dimensional matrix that is used to organize 15 theories of psychotherapy and to illustrate their relative emphases. For example, at the symptoms/situational level, motivational interviewing is located at the precontemplation stage and behavior therapy and exposure are located at the action stage. At the level of intrapersonal conflicts, psychoanalysis is suggested for the precontemplation stage, existential therapy is appropriate during contemplation, and Gestalt therapy is suggested for the preparation stage.

## Assimilative Integration

Assimilative integration starts with a firm grounding in one system of psychotherapy, but then incorporates or assimilates ideas or methods from other theories. Many psychotherapists feel comfortable selecting a primary theoretical orientation that serves as their foundation but, with experience, incorporate ideas and strategies from other sources into their practice.

Increasingly, integrationists are acknowledging that most counselors prefer the security of using one primary theory as they begin the process of exploration and integration.

George Stricker and Jerold Gold proposed an assimilative model based on relational psychoanalytic therapy but selectively incorporating more active interventions drawn from cognitive, behavioral, experiential, and systemic approaches. This approach is organized around a three-tiered model of psychological functioning that includes (1) behavior and interpersonal relatedness; (2) cognition, perception, and emotion; and (3) psychodynamic conflict, self-representations, and object representation. Psychotherapists are encouraged to look for links between these tiers and to be aware that interventions aimed at one tier may affect other levels of functioning.

Louis Castonguay's assimilative model rests on a cognitive-behavioral foundation that also includes techniques designed to facilitate interpersonal functioning and emotional deepening. This interpersonal focus on the therapeutic relationship allows clients to receive feedback about their actions and to understand the cause-and-effect links between the environment, cognitive and emotional processing, and the consequences of interpersonal behavior. From a behavioral perspective, emotional deepening can be seen as an exposure method that helps clients overcome a cognitive avoidance of affect.

### Emerging Models

In addition to these established approaches to integration, there are newer models that embrace ideas from more than one of the four established routes. The emerging models described next are also aimed at training counselors to begin thinking and acting in an integrative fashion from the very beginning of graduate school.

Clara Hill's three-stage model of helping skills combines theoretical integration and technical eclecticism; it encourages counselors to emphasize skills from different theories during different stages of helping. First, *exploration* is based on Rogers's person-centered theory, and it emphasizes skills like attending, listening, and reflection of feelings. Second, *insight* is based on psychoanalytic theory and uses skills such as challenge, interpretation, and immediacy. Third, *action* is based on cognitive-behavioral theory and emphasizes skills like giving information and direct guidance.

Glenn Good and Bernard Beitman's integration of common factors and technical eclecticism highlights both core components of effective therapy and specific techniques designed to target clients' particular issues or areas of concern. Counselors are encouraged to learn key concepts from a variety of psychotherapy theories. This approach emphasizes the importance of core processes related to therapeutic communication, working alliance, identifying patterns, and encouraging change. Attention is given to the specific skills that are most helpful when dealing with common concerns like depression, anxiety, and substance abuse.

Jeff Brooks-Harris's multitheoretical approach, a combination of technical eclecticism and theoretical integration, allows counselors to make informed choices when combining theories and intervention strategies. First, counselors are encouraged to systematically assess seven dimensions of functioning (thoughts, actions, feelings, biology, interpersonal patterns, social systems, and cultural contexts) and to choose the most salient dimensions on which to focus. Next, conceptualization is formulated using two or more theories corresponding to the selected focal dimensions. Finally, specific interventions are chosen from a catalogue of key strategies that are drawn from the theoretical approaches corresponding to each focal dimension.

### Therapy Relationships and Personal Integration

Most models of integration focus on the choice of intervention strategies, but the therapeutic relationship has even more impact on outcome than the choice of techniques. In response to this discrepancy, John Norcross and his colleagues described ways that the therapeutic relationship can be customized based on client characteristics including resistance, coping style, expectations, and attachment style. This integrative focus on the therapeutic relationship reminds counselors that any form of psychotherapy should be implemented within an interpersonal relationship based on a phenomenological understanding of the client.

Experienced counselors develop their own individualized and integrated conceptual systems and intervention styles over time. This process of *personal integration* involves an integration of the therapist's personal beliefs with formal theory, clinical experience, and therapeutic methods. Integrative psychotherapy can be seen as an art, and experienced therapists develop their own consistent, personal integrative

approach over time. Personal integration often begins as a form of assimilation with a foundation in one theory and takes on a unique appearance as it is adapted to the personal strengths of different counselors and implemented with different clients.

### Future Directions

Although integrative psychotherapy has become more popular, there are still obstacles to its further growth. Some persistent obstacles include continued allegiance to pure systems of psychotherapy and the difficulty of providing integrative training to graduate students. A more recent obstacle comes from those in the field who advocate the use of manualized treatments whose efficacy has been empirically supported using randomized clinical trials. Many of the integrative approaches described here are implemented in a flexible manner, based on the individual needs of clients. These types of treatment are difficult to manualize and are not consistent with the idea of randomized assignment to structured treatment protocols. In response to the need to document the efficacy of integrative treatments, there has been an increase in outcome research on psychotherapy integration. Although many counselors agree that psychotherapy should be evidence based, there is not always agreement about what evidence is most important.

It is likely that integrative/eclectic therapy will continue to be an important movement throughout the 21st century. New perspectives are likely to emerge that capitalize on the strengths of earlier approaches. Integrative psychotherapy will benefit from empirical research testing its usefulness, as well as continued clarity about how to balance research evidence and clinical wisdom. The consistent strength of integrative therapy will continue to be the recognition that complex individuals can be understood from a variety of vantage points, and effective counselors can combine therapeutic tools drawn from diverse theoretical sources.

## INTELLIGENCE

Historically, counseling psychology has emphasized cognitive constructs and measures in building models of optimal human development. The Internet and the widespread access to information from all over the globe, however, have transformed the world, making the identification and development of cognitive talent more important than ever. This entry focuses on the nature and organization of cognitive abilities; on their importance in educational settings, vocational settings, and other life contexts; and on dynamic aspects of intellectual dimensions.

### The Structure of Cognitive Abilities

Most psychologists agree that cognitive abilities are arranged hierarchically (see Figure 1). Within this hierarchy, general intelligence, or *g*, constitutes the apex and reflects the common factor that underlies all cognitive abilities. Group factors (or more specific, abilities) form the next tier of the hierarchy. These include specific abilities such as verbal, mathematical, and spatial reasoning (e.g., A, B, and C, respectively, in Figure 1). A large number of narrow abilities form the final stratum. These include skills such as verbal comprehension ( $A_1$ ), numerical facility ( $B_1$ ), and imagery ( $C_1$ ).

### General Cognitive Ability

General intelligence, or *g*, accounts for approximately half of the communality among heterogeneous collections of cognitive ability tests. It is assessed through combining many different kinds of cognitive tests to uncover what is common or shared among them. For example, a test that evaluates the ability to read a paragraph and understand its meaning and one that evaluates the ability to solve mathematical problems when presented in story form both require the ability to read and understand verbal material. Thus, while tests may appear to measure different abilities, they all assess to some extent a few basic underlying

abilities. It follows that *g* is the most important and all-encompassing ability underlying performance on tests of cognitive ability.

Thus, *g* represents one of the most scientifically significant dimensions of psychological diversity uncovered by the study of human individuality. It can be used to predict performance in educational and vocational contexts because both the tests that measure *g* and performance in those contexts require the use of *g*. The correlation coefficient is a standardized measure of how strongly variables are related to one another. It can range from +1.00 (a perfect positive relationship) to –1.00 (a perfect negative relationship). Measures of *g* are positively correlated with a wide range of important and fundamental life skills like practical knowledge, response to psychotherapy, social skills, altruism, supermarket shopping ability, preventive healthcare behaviors, and even a sense of humor. Furthermore, *g* is negatively correlated with obesity, racial prejudice, accident-proneness, smoking, delinquency, and impulsiveness.

Close to a century of research on cognitive ability tests has shown that *g* is also a good predictor of occupational outcomes. For example, *g* is a better predictor of job performance and trainability than any of the other numerous variables so far analyzed by researchers. Individuals who have higher levels of *g* perform at a higher level on the job because they more readily assimilate important knowledge that is necessary for performing effectively in the world of work.

The importance of *g* extends beyond educational and vocational contexts. Higher levels of *g* are also related to increased effectiveness in everyday life. Data from the National Adult Literacy Survey shows that higher levels of *g* consistently enhance the probabilities of dealing successfully with everyday life

**Figure 1** The hierarchical structure of cognitive abilities

events. In our technologically changing society, *g* matters greatly in many social and practical areas of life because it reflects individual differences in the capacity to process complex information and make effective decisions. Figure 2 summarizes the relation between intelligence and the likelihood of everyday life events. The illustrative occupations depicted at

each level of general cognitive ability are of course based on averages, but the ability ranges of the occupations at each level are similar.

Other models of intelligence have been proposed that are in theory distinct from the hierarchical model. Gardner's theory of *multiple intelligences* argues that there are at least seven independent "intelligences"

**Figure 2** Overall life chances at different ranges of IQ

Source: Adapted from Gottfredson, L. S. (1997). Why *g* matters: The complexity of everyday life. *Intelligence*, 24(1), 79–132.

and that conventional intelligence tests (that measure  $g$  as well as specific abilities) are too narrow. Gardner's seven "frames of mind" are linguistic, logical-mathematical, spatial, musical, bodily kinesthetic, interpersonal and intrapersonal, and naturalist. At least three of these (linguistic, logical-mathematical, and spatial), if measured appropriately, would largely overlap with  $g$  and with the specific abilities in the second tier of the hierarchical structure (i.e., verbal, quantitative, and spatial, respectively). Musical ability is likely related to  $g$  as well. Gardner's bodily kinesthetic, interpersonal and intrapersonal, and naturalist intelligences are not yet measurable in a way that permits a determination of where they might fit in the hierarchical structure of cognitive ability or of the extent to which they are related to  $g$  (see Figure 1). In fact, Gardner's bodily kinesthetic, interpersonal and intrapersonal, and naturalist frames of mind have not yet been adequately measured to date. For this reason, solid quantitative research evaluating Gardner's theory has not been published and evidence to support his theory remains absent.

Sternberg's *triarchic model* posits three independent kinds of intelligence: analytical, practical, and creative. Sternberg has developed measures of each of these forms of intelligence and has conducted studies that he claims support his model. However, independent researchers who have analyzed his data have concluded that Sternberg's three independent intelligences are not genuinely independent. It appears that  $g$  explains the variance in Sternberg's measures of the triarchic model.

### Specific Abilities

Despite the importance of general cognitive ability, there are specific abilities in the hierarchical structure (e.g., spatial visualization, quantitative reasoning, and verbal abilities) that have psychological value beyond  $g$ . One reason for this is that the level and pattern of specific abilities influence how individuals develop, even among individuals in the top 1% of general intellectual ability (i.e., at IQs greater than 137). This is illustrated in Figure 3. The four panels depict three critical developmental time points for intellectually precocious youth who were within the top 1% of general ability by age 13. These youngsters were assessed on spatial, mathematical, and verbal reasoning abilities at age 13 and then tracked longitudinally. At 5, 10, and 20 years later, individual differences in the level and pattern of these three abilities were linked in unique ways to distinct educational and occupational paths.

Panels A and B, respectively, indicate whether participants' favorite and least favorite high school course at age 18 was in the humanities/social sciences or math/physical sciences. Panel C outlines college major at age 23, and panel D shows occupation at age 33. Panel A shows that the favorite high school course of men and women who have above-average mathematical abilities (i.e., SAT-M greater than zero, which represents the standard score average), above-average spatial abilities (i.e., the arrow pointing to the right), and below-average verbal abilities (i.e., SAT-V less than zero) are likely to be in the math and physical sciences area. Those whose verbal abilities are above average and whose mathematical and spatial abilities are below average are more likely to mention courses in the humanities and social sciences as their favorite. To be clear, these standard scores were computed relative to this group of intellectually precocious youth, not the general population.

A repeated pattern across these panels is that participants with high levels of math and spatial abilities relative to verbal abilities ( $M$  and  $S > V$ ) are drawn to engineering and math/computer science fields (courses, majors, and occupations). In contrast, participants with high verbal abilities relative to math and spatial abilities ( $V > M$  and  $S$ ) prefer humanities and social science fields. Across these three points in time, information about the participants' spatial, mathematical, and verbal abilities added predictive power above and beyond the other two specific abilities in predicting these individuals' career preferences.

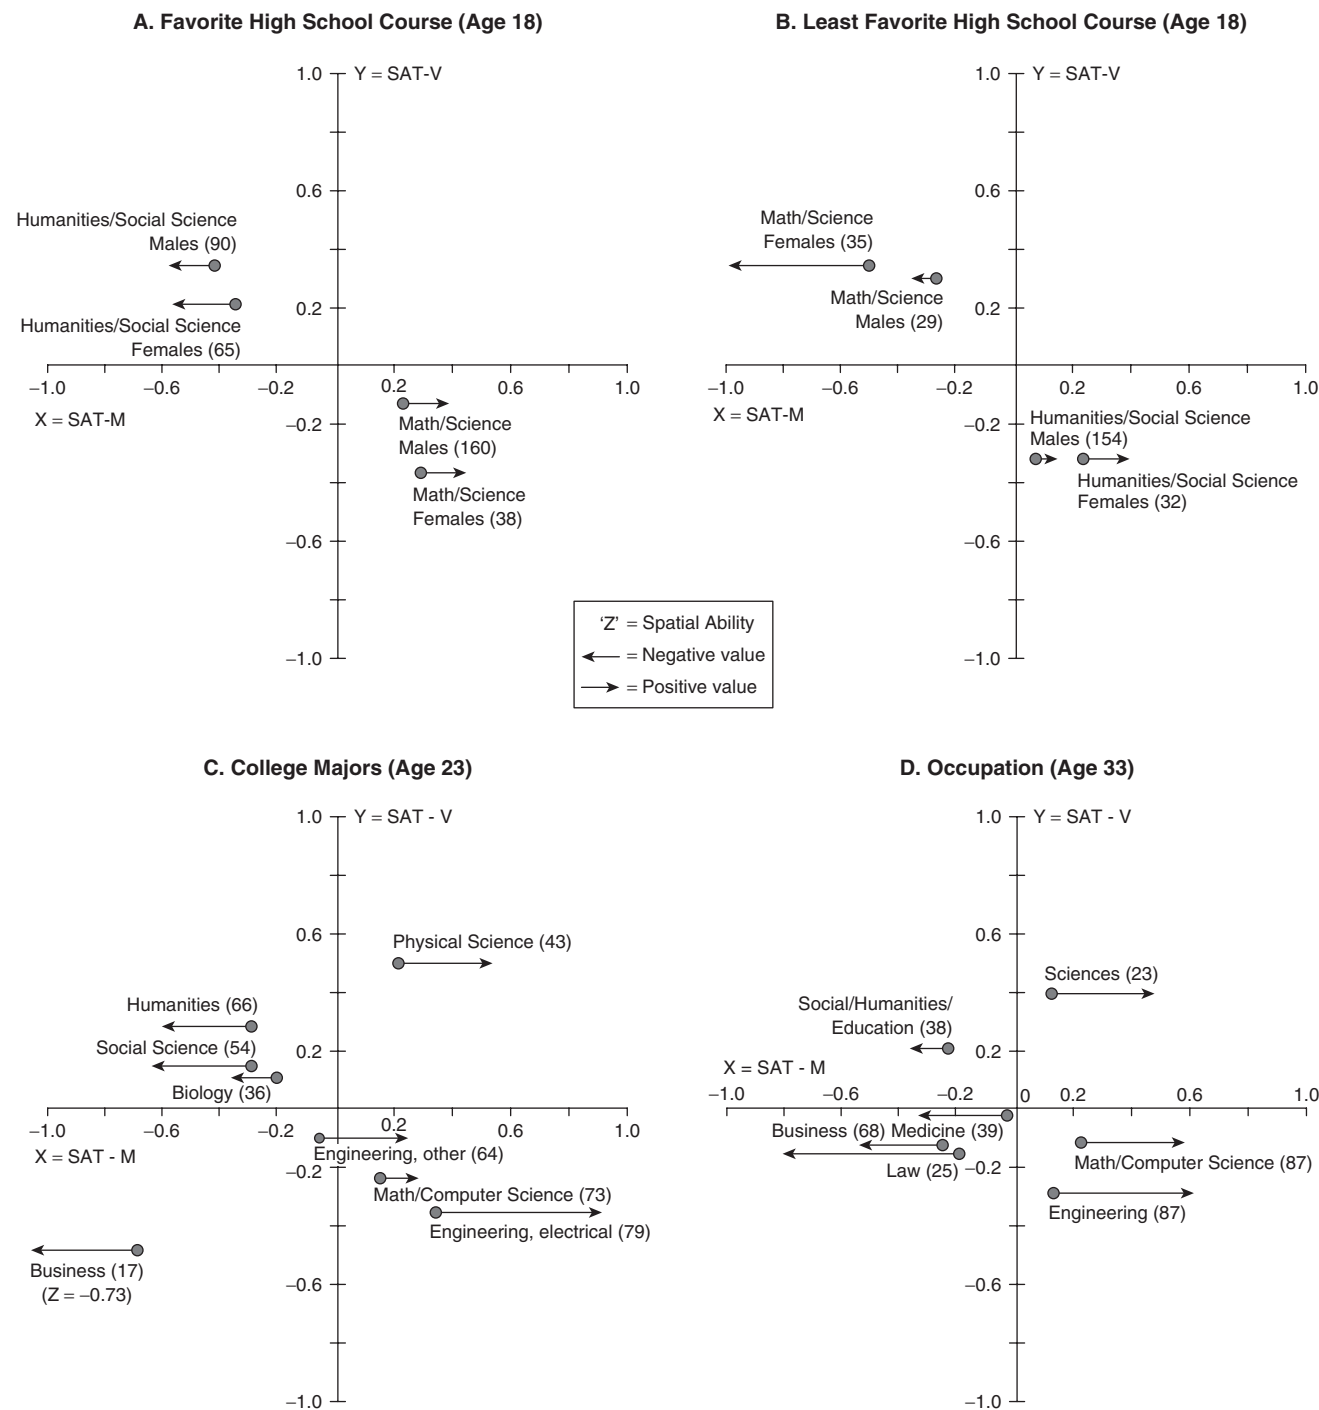

Another reason specific cognitive abilities are important is that their predictive power exists all along the range of general cognitive ability. One third of the ability range lies within the top 1% (e.g., IQs within the top 1% begin at around 137 and extend to over 200). A commonly held belief is that beyond a certain level of ability, more ability no longer matters. For example, a recent letter in *Science*, signed by Carol B. Muller and 78 additional academic administrators and research scientists, illustrates this widespread lack of understanding of how more ability matters in predicting educational, vocational, and thus life outcomes. This letter stated that those scoring in the upper range of standardized tests are unlikely to have more successful scientific careers because too many other factors are involved. Although other factors are involved, it is clear that other things being equal, more ability bestows an advantage.

One study evaluated this belief by examining whether students within the top 1% of cognitive ability before the age of 13 had differing educational and

vocational outcomes as a function of their ability level. This study examined the upper 25% and lower 25% of the top 1% in ability on the SAT-Mathematics. After more than 20 years, the top quartile outperformed the

bottom quartile on such diverse criteria as earning a doctorate, a high income, a patent, and tenure at a top 50 U.S. university (see Figure 4). Other studies examining even higher ability levels have demonstrated the same

**Figure 3** Career interests and career choices of talented groups differing on areas of relative strength

Source: Shea, D. L., Lubinski, D., & Benbow, C. P. (2001). Importance of assessing spatial ability in intellectually talented young adolescents: A 20-year longitudinal study. *Journal of Educational Psychology*, 93, 604–614. Copyright 2001 by APA. Reprinted with permission.

trend: More ability provides an advantage on comparable outcome variables when comparisons are made among highly talented individuals. In summary, technically sound investigations of the ability threshold hypothesis have shown unequivocally that this supposition is untenable. Cognitive abilities have the power to predict important criteria across the entire ability range.

### Dynamics

Heritability is the proportion of phenotypic variation in the population (i.e., variability in physical appearance such as eye color or manifestation of a specific trait such as aggressiveness) that can be attributed to genetic variation among individuals. There is an appreciable heritable component to  $g$ , and the heritability of  $g$  appears to increase over the life span. In

other words, genetic variations among individuals are one important contributor to the differences in  $g$  observed among individuals.

Both genetics and environment play a role in the development of individual differences in cognitive abilities. The part due to the environment is generally regarded as all of the nongenetic influences (i.e., both salient and less evident influences). The more apparent influences include an individual's opportunities for education as well as the educational, financial, and social level of the individual's parents. Less obvious influences include the effects of nutrition before, during, and after birth; hormones; and reduced health.

Although genes and environment are entwined, psychologists use biometric behavior genetic methods to identify the statistical contributions of these two factors to cognitive ability. A population statistic

**Figure 4** Comparison of two mathematically talented groups on four criteria

*Source:* Adapted from Wai, J., Lubinski, D., & Benbow, C. P. (2005). Creativity and occupational accomplishments among intellectually precocious youth: An age 13 to age 33 longitudinal study. *Journal of Educational Psychology*, 97, 484–492. Copyright 2005 by APA. Adapted with permission.

*Note:* These four panels represent the overall (combined across cohort and sex) proportion of participants in the lower 25% (Q1) and upper 25% (Q4) within the top 1% of ability on the SAT-Mathematics earning the respective criteria listed. The upper left panel includes both the percent earning a doctorate (entire bar) and the percent earning an STEM doctorate specifically (bottom segment of each bar). The remaining panels examine one variable each. The mean SAT-M for Q1 and Q4 were 455 and 629, respectively (achieved before age 13).

known as heritability is used to estimate how much of the variance in individual differences in intelligence is due to genetic factors. Psychologists estimate heritability by examining similarities among family members on the trait under analysis (i.e., the similarity to each other in *g* of identical twins, fraternal twins, parents and children, siblings, and adopted children). If individual differences in *g*, for example, are partly influenced by genes, then individuals who are more genetically similar should be correspondingly more alike on *g* (e.g., identical twins who share all their genes should be more alike than fraternal twins who share only half their genes).

Monozygotic (identical) twins who have grown up in separate environments provide a rare opportunity to assess directly the contribution of genes to individual differences in intelligence. Since the twins do not differ in genetic makeup, any difference must be attributable to environmental influences. Heritability can range from 0 (meaning no genetic influence on individual differences) to 1 (meaning individual differences are completely controlled by genetics). Heritability estimates for intelligence vary from approximately 0.4 to 0.8, but these values vary by age, with higher values indicative of later development. Overall, studies based on identical twins raised in separate environments generally indicate a heritability estimate of 0.7. Therefore, it is reasonable to estimate that 70% of the variance in intelligence among individuals is due to genetics.

Studies of adopted children provide another method of assessing the unique contribution of environmental differences to individual differences in intelligence. In the case of adopted children, the biological parents provide the genetic component and the adoptive parents provide the environmental component. Studies using this technique show that 30% or less of the variability in intelligence can be explained by the rearing environment. Thus, these studies provide the same general estimate ( $100\% - 30\% = 70\%$ ) as studies using identical twins reared in separate environments. Furthermore, for adults, this percentage drops to near zero, thus highlighting the dynamic aspect of heritability across the life span.

It is important to emphasize, however, that the large heritable component of intelligence does not preclude the possibility of the environment's influence on an individual's intelligence. Research conducted using animals reveals that severe cognitive deficits can occur when animals are reared in a cognitively sterile environment and that cognitive strengths can be fostered

when animals are reared in a cognitively rich environment. Lack of nutrition or lowered health has also been shown to have a negative impact on an individual's intelligence. Current research is investigating the genes relevant to specific and general cognitive abilities. One objective of the search for relevant genes is to discover what elements of the environment can be altered and which interventions can be implemented to increase intelligence. At present, this information is not known.

### **Phenotypic Growth**

Although cognitive abilities can be improved through learning, the relation between ability level and rate of learning is nonlinear. In other words, students learn at different rates and when students are given opportunities to learn at their optimal rate, those individuals who begin with more ability tend to benefit more from these opportunities. This is observed all along the ability spectrum. Students with developmental delays who are given the finest learning opportunities do not profit as much as typical students. At the upper end of the cognitive ability spectrum, students who scored 700 on the SAT (i.e., the top 0.01% in ability) when tested before age 13, benefited more from educational opportunities than those who scored 500 (i.e., the top 0.5% in ability).

E. L. Thorndike first reported this phenomenon in 1911 and psychologists have documented it repeatedly in the century since that time. Nevertheless, the nonlinear relationship between opportunities for optimal learning and corresponding increases in the level and variability of achievement as a function of ability is still not widely known. Most current articles and discussions do not mention this critically important phenomenon, and advocates of educational and social reform seem to be unaware of it. However, the finding is so robust that it has been christened the *first law of individual differences*.

### **The Flynn Effect**

Oftentimes, a heterogeneous verbal ability measure such as the SAT-Verbal or a nonverbal measure such as the Raven's matrices can provide functionally interchangeable estimates of general intelligence (i.e., both tests can be used to measure *g* to a similar degree). However, a broad ability measure such as the WAIS-R or the Stanford-Binet is necessary for certain avenues of research.

One issue that illustrates the important distinction between narrow and broad measures of intelligence is the meaning of the *Flynn effect*. This phenomenon, named after the scholar who first reported it, refers to the finding that IQ scores appear to have increased across each generation. However, careful analysis reveals that the magnitude of the Flynn effect varies across different assessment tools. Score increases on broad ability measures (e.g., instruments that sample spatial, quantitative, and verbal content) have changed the least. Larger gains have been observed on heterogeneous composites of verbal ability measures (i.e., summing scores on several tests, each of which measures primarily verbal ability). The greatest gains in IQ have occurred on the Raven's matrices. This instrument consists of nonverbal content (e.g., simple geometric shapes and lines that are arranged in a matrix). One cell of the matrix is empty, and respondents must select the element from among the choices offered that will complete the matrix.

This pattern is paralleled by the extent to which each of the aforementioned approaches to assessing IQ measures *g* (and cognitive ability components unique to the test). The Raven's has the least amount of *g* variance (about 50%) and the greatest nonerror uniqueness (40%). The remaining 10% of the variance in scores on the Raven's is attributable to random error. In contrast, broad measures of general intelligence have approximately 85% *g* variance, 5% nonerror uniqueness, and 10% random error. The heterogeneous verbal measures (such as the SAT-V) would be intermediate.

The two variance proportions that differ significantly are those of the *g* and nonerror uniqueness components. The latter component is most prominent in homogeneous tests like the Raven, less salient in heterogeneous composites of verbal measures, and only minimally present in heterogeneous composites that aggregate verbal, quantitative, and spatial abilities. The positive relation between the size of the Flynn effect gains and the variance attributable to the unique features of the test suggests that some of the reported increase in IQ scores is due to the unique components of the test used to measure *g*. In this instance the variance attributable to the unique features of the test is an irrelevant source of variation. Thus it appears that the Flynn effect gains do not reflect actual increases in *g* itself. Yet it is also possible that certain aspects of the Flynn effect are genuine. For example, scores concentrated in the lower end of

the bell curve may have increased due to modern advances in such factors as nutrition, health care, and immunization.

## Benefits

Psychometric assessments of intellectual dimensions, when combined with sound measures of other human attributes, are beneficial in helping people understand and explore the meaning of their individuality. An awareness of this important domain of psychological diversity is essential for all who are concerned with helping their children, students, and clients use psychological information about their strengths and weaknesses to establish and achieve their life goals.

## INTERPERSONAL LEARNING AND INTERPERSONAL FEEDBACK

---

Interpersonal learning occurs when individuals, through their interactions with others, acquire self-insight and learn new interpersonal skills. Interpersonal learning is facilitated through processes such as self-observation, self-reflection, feedback from others, and experimenting with new behaviors in an interpersonal context. Related therapeutic processes often occur in individual therapy (e.g., insight work, counselor feedback to the client, working through transference); however, within the counseling field, the term *interpersonal learning* is typically used to denote one of the major therapeutic factors associated with small counseling/therapy groups. A key mechanism through

which interpersonal learning occurs in the group setting is *interpersonal feedback*, in which members share their reactions to, and perceptions of, each other's behaviors.

## Interpersonal Learning in Group Counseling

### *Historical Perspective*

In 1955, Raymond J. Corsini and Bina Rosenberg were the first to present a comprehensive classification of group therapeutic factors. William F. Hill and others presented their own models within the next few years. These classifications included elements of interpersonal learning; however, the term *interpersonal learning* was first proposed by Irvin D. Yalom in his 1970 landmark classification of group curative factors.

Yalom's development of interpersonal learning dimensions had a major influence on later group curative factor classifications. For example, in 1985, Sidney Bloch and Eric C. Crouch presented a model of group therapeutic factors that included "learning from interpersonal action" and "insight (self-understanding)." Together, these two factors closely resemble Yalom's interpersonal learning dimension.

In comparative studies of group therapeutic factors, research findings from the 1970s to the present have consistently ranked interpersonal learning among the most helpful elements in the group process.

### *Therapeutic Factors in Group Counseling*

Therapeutic factors refer to those forces in counseling groups that flow from the interactions among group members (including the group leader or coleaders). These forces promote and support group members' efforts to gain self-insight, pursue goals, and make productive changes in their lives. Some examples of group therapeutic (or curative) factors include cohesiveness, universality (the realization that one's problems are not unique and that others face similar challenges), instillation of hope, and interpersonal learning.

Interpersonal learning is often cited as one of the most important therapeutic factors. Interpersonal learning is particularly important in groups oriented toward member self-insight and the development of social interaction skills (e.g., personal growth groups, encounter groups, and interpersonal groups). Because psychological disturbances are often the result of

underlying problematic interpersonal relationships, interpersonal learning serves as a valuable means of directly addressing such issues.

### ***The Interpersonal Learning Process***

As members of a counseling group interact among themselves and the group leader, they tend to engage in the habitual patterns of behavior that are characteristic of their interactions in social situations outside of the group setting. Both effective and ineffective social behaviors are on display for other members of the group to observe. In effect, a social microcosm is created whereby members get to see each other as they really are. This provides an ideal environment for the interpersonal learning process.

In his formulation of interpersonal learning, Yalom included both input (gaining insight from others' feedback) and output (trying out new behaviors in the group) dimensions. He also emphasized certain elements that mediate the therapeutic effects of interpersonal learning. The social microcosm of the group must provide a safe and supportive environment for members to be themselves and express here-and-now feelings. Also it must at the same time foster honest feedback and the opportunity for reality testing (e.g., for members to compare their perceptions to the perceptions of others). Members must be able to experience intense emotional awareness of the effects of their interpersonal behavior, both in terms of their feelings about themselves and in terms of others' reactions. In essence, a given group member undergoes a corrective emotional experience whereby the individual is re-exposed, within the supportive group environment, to emotional situations that could not be effectively handled in the past. Through such emotional awareness the member can be motivated to develop cognitive understanding by examining and interpreting the experience with the help of other group members.

The interpersonal learning process is likely to follow a cycle that typically begins when a given group member displays a problematic behavior (e.g., constantly criticizing others, dominating the discussion, denying strong feelings, expressing distorted perceptions). The member then observes others' reactions and/or receives feedback from others and engages in reality testing through consensual validation (confirming the validity of the feedback with multiple group members). With the help and support of other group members, the member may then reflect on and accept responsibility for the

consequences of the problem behavior. As a result of such reflection, a decision may be reached by the member to work on changing the ineffective behavior. With the help of others in the group, the member can then work to develop new, more effective behaviors and practice them in the group. This sequence is then recycled as the member receives feedback concerning new behaviors. As more effective interpersonal behaviors are gradually developed, the individual receives increasingly positive feedback which leads to increased confidence and self-esteem as well as an increased willingness to experiment with other new behaviors. Throughout this process, the group leader seeks to facilitate each step and, ultimately, to facilitate the generalization of new, more effective behaviors to functioning outside the group setting.

### **Interpersonal Feedback as an Element of Interpersonal Learning**

Interpersonal feedback represents one of the most direct means by which individuals can learn about themselves from others, and it is widely considered to be a key element in the interpersonal learning process. Interpersonal feedback can be described as sharing one's reactions to another's behavior, and perceptions of that behavior, with that person. This allows the receiver of the feedback to gauge the extent to which others perceived the behavior as it was intended.

The group counseling setting provides a particularly rich environment for the exchange of feedback. Most therapeutic groups are composed of a group leader (or coleaders) plus three to eight group members, providing each member with the opportunity to receive feedback from multiple sources. Strong consensual validation occurs when feedback from multiple sources is in agreement and the recipient cannot dismiss the feedback without careful consideration and self-reflection.

### ***Positive and Corrective Feedback***

Two basic types of helpful feedback exchanged among group members are *positive* and *corrective* (sometimes referred to as *negative*). Positive feedback is often given in the form of praise for behaviors that are considered effective and desirable. Corrective feedback usually takes the form of encouragement to become aware of and reflect on a behavior that seems ineffective or inappropriate from the feedback giver's

perspective. Positive feedback tends to be readily received by most group members. Corrective feedback, though considered essential for the process of modifying ineffective behaviors, may arouse anxiety and be difficult for the receiver to accept and utilize, especially during the early stages of group development.

### **The Effective Exchange of Feedback in Groups**

Group leaders may follow (and encourage group members to follow) certain general guidelines in order to provide a group atmosphere where feedback (especially corrective feedback) can be used productively. For example, research findings have indicated that corrective feedback is usually more effective when delivered after group members have progressed beyond the early stages of group development and group cohesion is relatively high. Corrective feedback is also likely to be more readily accepted when it immediately follows positive feedback, a trusting relationship exists between the giver and receiver, the feedback focuses on specific and observable behaviors rather than being evaluative, and when the receiver has the opportunity to seek clarification and receive help in processing the feedback information.

### **Future Directions**

Interpersonal learning will likely continue to be viewed as one of the most important therapeutic factors operating in counseling groups. Researchers are increasingly focusing on studies to clarify the relative importance of interpersonal learning and other therapeutic factors across the various developmental stages of groups as well as for differing client populations. Additionally, much work is being done to determine which therapeutic factors are most important for particular types of group experiences. Dennis M. Kivlighan, Jr., and Stacey E. Holmes, for example, presented findings of a 2004 meta-analytic study from which they formed a typology of groups based on their therapeutic mechanisms. They concluded that group members ranked interpersonal learning as highly important for groups focused on affective or cognitive insight, but as somewhat less important for groups focused on affective or cognitive support. It seems likely that future research studies will increasingly seek to clarify the unique contributions of interpersonal learning (and component elements such as

interpersonal feedback) as well as the means by which group leaders can most effectively initiate and enhance its facilitative effects.

## **INTRINSIC MOTIVATION**

---

Intrinsic motivation occurs when an individual engages in an activity solely because the activity is perceived and experienced as interesting and enjoyable and not because of any external incentive or inducement to do so. Historically, intrinsic motivation has been distinguished from amotivation, which refers to a lack of drive or energy to engage in an activity, and extrinsic motivation, which occurs when someone engages in an activity for some reason other than the sheer interest and enjoyment of the activity. Contemporary models of intrinsic motivation vary in the extent to which they explore the subjective experience of interest and the role it plays in self-regulating behavior. However, all perspectives acknowledge the influence of various situational and individual factors on interest and intrinsic motivation. The integration of these contemporary models with research on emotion, cognitive appraisal, and self-regulation will further advance the applicability of intrinsic motivation research to education, work, and mental, emotional, and physical health.

## The Nature of Intrinsic Motivation

### Definition

In Latin, the root of the word *motivation* means “to move.” The study of motivation involves the attempt to understand why people engage in certain activities (e.g., work, school, social relationships, personal health and fitness) and includes studying the choices people make and whether and how they continue to engage in activities once they begin.

A phenomenological perspective is essential to adequately grasp how social scientists conceptualize intrinsic motivation. In other words, it is necessary to try to understand the subjective experience of the individual, including the personal meaning, importance, and value the individual places on certain activities and the feelings of interest and enjoyment the individual feels. These value- and feeling-related variables are generally positively correlated with one another; however, they may relate somewhat differently to people’s activity choices and their continued involvement in activities over time.

Psychologists conceptualize intrinsic motivation in three ways. Educational and sport psychologists, in particular, conceptualize intrinsic motivation as an individual difference characteristic, traitlike in nature, and they use self-report scales to measure differences in motivation among people. In general, these scales assess differences in people’s preferences for challenging activities, their strivings for competence and mastery, and their perceived interest in certain activities. Other researchers conceptualize intrinsic motivation as a situational characteristic. These scholars examine how altering certain aspects of an activity influence the degree to which the activity is perceived as interesting. For example, researchers have examined the extent to which novelty, sex-typing, performance feedback, and the actual presence of other people affects interest in an activity. A third group of scholars, recognizing that individual and situational factors are likely to influence motivation, examines the ways in which activity characteristics, individual differences, and contextual factors combine to influence interest and motivation.

Although researchers have measured intrinsic motivation in a variety of ways, two measures are most often used. One commonly used method is to ask participants to rate their interest and enjoyment after engaging in an activity (i.e., self-report). The second method involves a behavioral measure of interest during a “free choice” period. In experiments

using this method, participants engage in a specific task under varying conditions (e.g., praise vs. no praise). After finishing the task, the experimenter tells the participant that he or she will not be working with the task any longer. Then, the participant is left alone in the lab with the original task and several distractor tasks for a period of time. During this period, the participant has free choice to engage in any or none of the tasks in the room. The amount of time the participant spends with the experimental task during the free choice period, when no extrinsic reason is in place, is considered the measure of intrinsic motivation.

### A Brief History

People have been pondering the distinction between motivation arising from within the individual and motivation derived from some external source at least as far back as writings attributed to Confucius (551–479 B.C.). As a behavioral phenomenon, intrinsic motivation was initially described in the 1940s and 1950s in experiments with nonhuman animals. In these experiments, animals were observed to engage in exploratory behaviors, appearing curious and playful, even in the absence of any external reinforcer.

The contemporary concept of intrinsic motivation as it relates to human behavior developed as a challenge to learning and behavioral conditioning theories prominent in the field of psychology from the 1940s through 1960s. Operant conditioning theory asserted that people engaged in activities because of the nature of the reinforcements they received as a consequence. In contrast, the concept of intrinsic motivation highlighted that for some activities, the reward came from doing the activity itself, not from what happened after. Even though some learning theories allowed for motivation as a cause of behavior, these theories focused on motivation based on satisfaction of basic physiological needs (e.g., hunger, thirst, sex), or on satisfaction of learned needs that at one point were associated with basic physiological needs (e.g., motivation to obtain money). Initial conceptions of intrinsic motivation, in contrast, highlighted the possibility that some activities were motivated by basic *psychological* needs (e.g., personal causation, competence).

Over the next 40 years, intrinsic motivation research was guided by the proposition that the motivation to satisfy specific psychological needs (e.g., competence, autonomy, relatedness) was the energy source for intrinsically motivated activities. More

recently, the state of intrinsic motivation itself (i.e., the feeling of being interested and immersed in an activity) became a focus of attention due to research suggesting that the satisfaction of these basic needs does not necessarily result in intrinsic motivation. This research highlighted the need to distinguish between the state of intrinsic motivation and the conditions that make it more or less likely to occur. Recent work has also started to focus on the process through which the state of intrinsic motivation may turn into well-developed individual interests that are characterized by extensive knowledge of, valuing of, and long-term commitment to, a particular topic or domain in life.

### Contemporary Models

The following three models were selected to illustrate the different underlying assumptions that have been made regarding the nature of intrinsic motivation. These assumptions have implications not only for how intrinsic and extrinsic motivation are related to one another, but also for how these two forms of motivation relate to other situational and individual characteristics.

#### Flow Theory

The purest and most intense subjective experience of intrinsic motivation has been labeled *flow*. Flow describes the emotional state and change in consciousness that occur when people engage in *autotelic* activities (i.e., activities people do for the activity's own sake rather than for some type of extrinsic reward). *Flow* became the descriptor for this experience after several participants in research studies of certain autotelic activities (e.g., rock climbing, chess, painting) reported that when they were engaged in the activity they felt as if a current were carrying them along effortlessly. This state has also been described as feeling immersed in, or being carried away by the activity, in such a way that one loses one's sense of a separate self.

The defining feature of flow is an intense moment-to-moment involvement in an activity. After the experience, people often report having felt a heightened sense of control, a merging of awareness and action, and an altered sense of time. Although intense flow experiences are relatively uncommon in people's everyday lives, many activities are capable of producing them as long as several conditions are met. First, flow is more likely to occur when a person is engaged in an activity that has a clear set of goals that serve to direct attention to the activity. Second, the person

must feel a balance between the requirements and challenges of the activity and his or her own abilities. When this balance between activity requirements and personal skill exists, the individual's attention is completely absorbed in the activity. When this balance is not present, the person is more likely to experience anxiety if the challenges are perceived as too difficult, or boredom if the activity is perceived as too easy. A final condition that increases the likelihood flow will occur is the presence of clear, immediate performance feedback that enables the person to engage in corrective action. The experience of flow is psychologically rewarding, and participants often comment that they enjoyed an activity so much they would be willing to go to great lengths to experience it again. In order to induce further flow experiences, individuals must seek out increasingly difficult activities as they master skills and challenges. Therefore, the experience of flow itself is assumed to reinforce behaviors underlying human growth and development.

#### Self-Determination Theory

Self-determination theory (SDT) rests on the assumption that people are active organisms, innately motivated toward growth and development. Consequently, people naturally seek to experience optimal levels of stimulation, mastery over challenges, and a sense of volition and choice (i.e., self-determination). The social environment may either aid or thwart people's abilities to meet their basic needs for competence, autonomy, and relatedness.

Within the general SDT framework, *cognitive evaluation theory* focuses on how feedback, praise, and rewards influence a person's intrinsic motivation, based on whether these social factors are perceived by the person as controlling or as information about his or her competence. Events that lower feelings of autonomy will interfere with intrinsic motivation, whereas events that convey positive competence information will enhance intrinsic motivation. From this perspective, an event does not have to be external to have detrimental effects on intrinsic motivation. Internally generated constraints (e.g., internalized pressure to perform well) may also result in lower intrinsic motivation.

This early recognition led to more recent developments within SDT that suggest that motivation can be thought of not just in terms of the distinction between intrinsic and extrinsic motivation but also as existing along a continuum of autonomy or self-determination. The proposed continuum ranges from amotivation on

one end (the least self-determined) to intrinsic motivation on the other (the most self-determined). In between are four types of extrinsic motivation (external, introjected, identified, and integrated) that differ in the degree to which they are experienced as autonomous, freely chosen and arising from important aspects of the self. The two relatively more autonomous forms of extrinsic motivation (i.e., identified and integrated extrinsic motivation) are distinguished conceptually from intrinsic motivation. However, in research and practice, these distinctions are frequently disregarded because these forms of motivation often have similar positive effects on persistence and effort, and on physical and psychological well-being.

The self-determination continuum has been used to help predict effects of different situational variables on behavioral and psychological outcomes, as well as to provide a basis for the development of individual difference measures. These latter measures attempt to identify consistent differences in particular domains (e.g., education, sports) or between individuals in terms of the degree to which they approach situations with self-determined orientations.

### ***Self-Regulation of Motivation Theory***

Although self-determined extrinsic motivation and intrinsic motivation may often have similar effects on outcomes, self-regulation of motivation theory (SRM) suggests that distinguishing between intrinsic and extrinsic motivation may be important in understanding the motivational process. SRM theory is based on the assumption that maintaining motivation to engage in a particular activity over time requires that people have some level of both extrinsic and intrinsic motivation. Feelings of “having to” (i.e., extrinsic motivation) may be essential because the activity may lead to some important outcome; and so it may be critical to persist even when the experience is not interesting. In turn, feelings of “wanting to” (i.e., intrinsic motivation) are essential because it is difficult and stressful to persist indefinitely when one dreads the experience. From this perspective, extrinsic and intrinsic motivation may be bidirectionally integrated into an individual’s self-regulatory process over time. For example, research has shown that an extrinsic reason to value a boring activity (self-determined extrinsic motivation) can lead to intrinsic motivation, by motivating the person to engage in strategies that make doing the activity more interesting. Moreover, engaging in

interest-enhancing strategies can, in turn, lead to seeing the activity as more valuable.

A critical task of self-regulation, therefore, is to regulate both kinds of motivation when and if needed. In other words, intrinsic motivation is embedded in people’s everyday regulation of behavior. Rather than being a rarity, limited to special flow experiences, interest and enjoyment are crucial for the continued performance of activities people deem important to their everyday lives. This perspective suggests that the absence of interest may be an important (and underrecognized) source of motivational and affective problems. For example, the absence of interest during the process of activity engagement may lead individuals to discontinue the activity or to select alternative activities, even when this means foregoing important positive outcomes. Some researchers have suggested that certain problem behaviors among individuals with psychiatric disorders (e.g., failure to sustain treatment) may in fact be reactions to boredom, particularly for individuals beginning to recover from psychotic breaks. Moreover, if individuals attempt to regulate their interest in an activity rather than quitting the activity, the particular strategies they use might be considered off-task or inappropriate, resulting in negative evaluations by others and other negative consequences.

By embedding intrinsic motivation within the everyday self-regulatory process, this perspective illuminates potential implications for the relationships between goals and the experience of interest. For example, rather than identifying certain types of goals as inherently intrinsic or extrinsic, the key is identifying whether working toward a particular goal is associated with the experience of interest for a particular individual. An individual is likely to experience greater interest when the context is congruent with (i.e., matches) his or her goals, and when multiple goals are compatible with each other. Intrinsic motivation does not just depend on particular characteristics of a task or situation, therefore, but rather is a dynamic state that arises through an ongoing transaction among individuals’ goals, activity characteristics, and the surrounding context over time.

### **Related Situational and Individual Factors**

#### ***What Makes Something Interesting?***

Researchers have identified various characteristics of activities and situations that influence the degree to

which an activity is perceived as interesting. For example, the addition of fantasy story lines and the addition of information to make the activity personally relevant can enhance students' interest in educational video games. In general, activities that arouse curiosity, allow people to act effectively, or allow involvement in fantasy tend to be those that individuals find interesting. In contrast, external constraints on behavior interfere with a person's interest in an experience. For example, rewards made contingent on performing an activity that the person would have done anyway because of interest tend to decrease subsequent intrinsic motivation to perform the activity. Rewards made contingent on performing well, in contrast, have a more complex set of effects. Working with other people can lead to greater interest, particularly for some individuals. The next section describes the role of individual differences in understanding what leads to greater or lesser interest.

### *Is It Interesting to Me?*

Researchers have identified a variety of individual differences that serve to moderate the influence of particular activity and situational factors in fostering interest. For example, individuals higher in interpersonal orientation may experience greater interest when working on activities *with* others (assuming that the interpersonal interactions are positive). In contrast, individuals higher in achievement orientation may experience greater interest when working on activities that involve competition *against* others.

Clearly, a wide variety of factors influence activity interest. Yet, how do people decide for themselves whether or not an activity is interesting? The appraisal structure of interest model assumes that interest works similarly to other emotions, resting on an appraisal of the situation and people's capacities to respond. According to the model, people's perceptions of novelty (i.e., the unfamiliarity and complexity of an activity) and their coping potential (the degree to which people believe they can understand a new and complex activity) are two factors influencing the degree to which interest is experienced. People's coping potential encompasses their appraisals of whether they have the resources, skills, power, and personal control to handle the activity effectively. When people approach a novel activity believing they can understand and handle it, they are more likely to experience interest. Over time, the emotional experience of interest may

guide the development of enduring personal interests in certain kinds of activities.

## **Applications of Intrinsic Motivation Theory**

Scientific understanding of the essential role of intrinsic motivation in human motivation and the self-regulation of behavior has been applied to a wide variety of social contexts, including education, health care, parenting, exercise and sports, and work and organizations. Following are several examples of how theory and research on intrinsic motivation have been applied in different domains.

A number of researchers interested in achievement behavior have recognized the important interplay between achievement goals and intrinsic motivation. Traditionally, two types of achievement goals have been distinguished. *Mastery goals* involve attempts to learn and increase one's competence, whereas *performance goals* involve attempts to maximize positive evaluations of competence and minimize negative evaluations. More recently, performance goals have been subdivided into two types: goals to display competence relative to others (*performance-approach goals*) and goals to not appear incompetent relative to others (*performance-avoidance goals*). Research has indicated that mastery goals are positively correlated with interest and enjoyment of learning, hope, and pride as well as with academic performance and prosocial behavior in the classroom. The effect of performance goals is less clear. However, performance-approach goals tend to have more positive consequences for motivation than performance-avoidance goals, and depending on the context (e.g., whether in the classroom or the lab) and individual differences in achievement orientation, their positive effects on interest may be equivalent to the effects of mastery goals.

The SRM model has been applied effectively to understanding individuals' vocational and career choices. Indeed, interest is a main reason people give for their career choices. One question that has been examined concerns why women are less likely than men to choose careers in math, computer technology, and the physical sciences. According to the SRM model, people's career interests are influenced by the degree of match or congruence between their personal work goals and their perceptions of the extent to which different careers offer opportunities to pursue those goals. Women are more likely than men to value

opportunities to work with and help other people, whereas men are more likely than women to value opportunities for high pay and recognition. Both women and men perceive math, computer science, and physical science careers as offering fewer opportunities to work with and help other people and more opportunities for high pay relative to several other career options. One consequence of this gender difference in match between individuals' work goals and their perceptions of different careers is that women and men are likely to find certain career options relatively more or less interesting to pursue.

Sport psychologists have used the concept of intrinsic motivation, both as a situational and individual difference characteristic, to study a number of different phenomena. As a situational characteristic, researchers have examined the effects of performance feedback and coaching climate on people's intrinsic motivation and goal pursuit. As an individual characteristic, intrinsic and extrinsic motivational orientations for athletic involvement have been linked to different levels of alcohol use among college students. Specifically, college athletes and exercisers who were intrinsically motivated toward athletics reported less use of alcohol than did those who were extrinsically motivated. A rather unique element of applied research in this domain is that individuals in a wide age range (i.e., from early childhood to older adulthood) have been included.

Applications of intrinsic motivation theory to general counseling contexts have examined myriad forms of behavior, including the development of parenting skills, offender recidivism, and adherence to therapy regimens.

### The Ongoing Debate

The earliest experiments on intrinsic motivation in the early 1970s found that tangible extrinsic rewards decrease intrinsic motivation. These results were highly controversial because they challenged the predominant behavioral perspective that asserted that carefully constructed reinforcement contingencies were the most effective way to increase motivation. Since that time, nearly 100 published studies have supported the original finding, yet the debate continues. Some behaviorists maintain that rewards do not decrease intrinsic motivation and advocate the use of reward-based incentive systems in schools. Intrinsic motivation researchers respond by emphasizing the need for caution when implementing such systems.

Researchers on both sides of the debate acknowledge the complex effects of rewards on motivation. For example, over the past 20 years the effects of using performance-contingent rewards (i.e., rewards contingent on doing well on a task, not just completing it) have been shown to be distinct from other types of reward. With performance-contingent rewards, individuals who succeed receive something tangible as a symbol of their excellence. Three properties of performance-contingent rewards (i.e., the psychological pressure arising from knowing one is being evaluated, the fact that the reward clearly conveys task competence, and the symbolic cue value of the reward) simultaneously affect motivation in both positive and negative ways. For example, the performance pressure from being evaluated can negatively affect motivation, whereas the positive performance feedback upon the reward's receipt can enhance motivation. By providing a tangible symbol of accomplishment, the reward can also increase interest independently of the positive performance feedback by intensifying the emotional significance and importance of the accomplishment (this may help to explain the popularity of trophies and plaques). This third property of performance-contingent reward can thus enhance interest when rewards are obtained, by making the competence level achieved more tangible and valued. However, the same property may diminish interest when individuals fail to qualify for the reward, because the failure also has greater impact.

These research findings are directly relevant to the current high-stakes testing debate in public education. High-stakes testing is endorsed by some as a way of increasing motivation and performance among students, teachers, and school administrators. Students, teachers, and schools performing at or above state or federal standards are rewarded and those failing to meet standards are punished. The results of extensive research on intrinsic motivation over the past 30 years led to the conclusion that the use of such practices is likely to be harmful to students' and teachers' interest in, and enjoyment of, learning.

### The Future of Intrinsic Motivation

A major concern of psychologists over the next 20 years will be to increase their understanding of the manner in which intrinsic and extrinsic motivation, emotion, cognition, and goal-seeking interact to shape

the self-regulation of motivation and behavior. There will likely be continued movement away from the position that intrinsic and extrinsic motivation are two ends of a continuum and greater recognition of the fluidity and gradations between these forms of motivation and their simultaneous existence. The integration of existing models of intrinsic motivation (e.g., flow theory, SDT, SRM, appraisal structure of interest theory) within the broader field of positive psychology opens up enormous opportunities for social scientists whose goals are to enhance quality of life and well-being.

## JUNG, CARL (1875–1961)

---

Carl Gustav Jung was a Swiss-German psychoanalyst who, with Sigmund Freud, was instrumental in ushering depth psychology (theories of the unconscious) into the 20th century.

Jung was educated at the University of Zurich and as a young man he developed the concept of the autonomous, unconscious complex and the technique of free association, well before joining forces with Freud's Viennese School. Along with Alfred Adler and Sigmund Freud, Jung worked to advance the concept of unconscious motivation. Despite their initial collaboration, however, Jung broke with Freud over the latter's reductionist, psychosexual view of the unconscious and his own espousal of phenomena that Freud regarded as occult.

Just before the outbreak of World War I, Jung experienced a spontaneous series of "visions" that nearly led him to psychosis. These visions awoke in him a revolutionary appreciation of how close his own unconscious life was to the primitive myths and rituals of humankind. The importance of occult experiences was apparent in Jung's first published paper, "On the Psychology and Pathology of So-Called Occult Phenomena." In Jung's writings, the unconscious encompassed not only the biological drives that Freud had emphasized, but also those "spiritual" or occult aspirations that Jung believed were just as integral and innate a part of human individuality. Thus, Jung acknowledged forces within the human psyche for which the Freudian view had little explanation. This fundamental difference in their view of the human personality ultimately led to their break.

In formulating his theories on the collective unconscious and the archetypes, Jung posited an unconscious—and hereditary—source for all of humankind's creative endeavors and spiritual yearnings. Jung divided the unconscious into two levels. The *superficial personal unconscious* houses memories that are too weak to reach consciousness, and memories and traumas that are so threatening they are suppressed by the ego. The *collective unconscious*—sometimes referred to as the *racial memory*—is the repository of the universal religious, spiritual, and mythological symbols and experiences of humankind. The primary structures of the collective unconscious that form the foundation of the human psyche are the archetypes. Jung believed these structures are biologically based and inherited.

Jung defined the *archetype* as a "primordial" psychic image or pattern, representative of our ancestral experiences, that recurs throughout human history in dreams, fantasies, myths, and art. The major archetypal figures of the collective unconscious, Jung proposed, are the shadow, anima, animus, and self. The *shadow* is the amoral, prehuman, animal aspect of personality that is instinctively focused on reproduction and survival. The *anima* is the female aspect of personality present in the collective unconscious of men. The *animus* is the male aspect of personality present in the collective unconscious of women. The *Self* is the unified personality that integrates conflicting aspects of the personality such as the anima and animus. The unconscious is centered around the Self.

Jung also developed a groundbreaking personality theory that introduced the concepts of extraversion and introversion, and that explained human behavior as a combination of four psychic functions—thinking, feeling, intuition, and sensation. (This psychological

typology would provide the theoretical foundation for the well-known Myers-Briggs personality survey.) Other crucial Jungian formulations include compensation, synchronicity, and individuation. *Compensation* refers to the ongoing efforts of the unconscious to correct the ego's one-sided view of reality. *Synchronicity* reflects the importance Jung attributed to occult events. He believed that some meaningful events are not the result of mechanistic causation nor of human intention. Most psychologists and laypersons would call these events coincidences, but Jung believed they are indications that we are connected with other humans and with nature in general through our collective unconscious. *Individuation* refers to the lifelong psychological process of the ego's encounters with, and acceptance of, the archetypes within, especially the unconscious Self.

Jung spent his later years beside Lake Zurich carving in stone the mythological figures to which he had devoted his life. For example, Jung represented the Self as the circle, cross, and mandala. One possibly apocryphal story is that on the night of Jung's death, thousands of his friends and disciples throughout the world dreamed of his passing, and his favorite tree beside the lake was split in two by lightning. Whether true or not, Jung would most certainly have been delighted, for the story honors his lifelong advocacy of occult experience and illustrates his concept of synchronicity, namely, that all humans are connected through the collective unconscious. Perhaps now he was a part of that collective realm that had been the great subject of his life's work.

## LANGUAGE DIFFICULTIES, CLINICAL ASSESSMENT OF

---

The terms *language*, *speech*, and *communication* are used interchangeably by most people. When children or adults are seen by a speech-language pathologist (SLP), however, each of these terms refers to specific behaviors that are assessed and treated differently.

*Language* is a symbolic code organized by rule-governed combinations that are socially shared. Children learn to use this symbolic code by being part of families and communities. This learning process continues when children go to school and learn to read and write and formally study language. Most children have no difficulty learning the code. They quickly and easily recombine words to talk with others (which can be likened to building structures with a Lego set). However, approximately 10% of all children have difficulty learning some aspect of the language code. In addition, some adults have had an experience, for example, a stroke or head trauma, that resulted in specific language impairment.

*Speech* is the spoken production of language. It is an oral neuromuscular process that shapes the sounds particular to each national language and allows verbal transmission of thoughts and ideas between people. The mouth's structures and muscles shape the sounds, but the sounds being shaped are particular to specific symbolic language codes.

*Communication*, the most comprehensive of the three terms, involves the exchange of information between people. This exchange can be *nonverbal*, such as when the body, space, and eye gaze are used to

convey information. It can be *vocal*, such as when those who are hearing impaired or using electronic equipment add their pitched voice, grunts, and so forth to the messages they are sending. It can be *verbal*, such as when information is exchanged by speaking to one another. Language is integral to communication because this symbol system is used to encode information and ideas. Therefore, while language need not be spoken, it is a pivotal aspect of communication.

Language, speech, and communication typically co-occur in everyday life. When considering atypical development or disease, injury, or illness that affects language, each person must be assessed and possibly treated differently. A life-span perspective about language assessment follows.

### ***Birth to Age Three***

Infants who are born with health problems, syndromes, or into living situations that place them socially at risk are eligible to receive early intervention services. The goal of these services is to prevent or reduce the effects of the biological or social conditions on development. Transdisciplinary teams provide services in homes and centers under an Individual Family Service Plan (IFSP). The family rather than the infant alone is considered the client.

Since the development of language is fundamental to communication and later learning, the SLP assesses emerging skills and formulates an intervention program. The focus of the assessment shifts between communication, speech, and language, depending on the developmental status of the infant. Common assessment tools include the Rossetti Infant and Toddler

Language Scale, Receptive-Expressive Emergent Language Test, Sequenced Inventory of Communication Development, and MacArthur Communicative Developmental Inventories. These scales are criterion-referenced instruments that report age equivalencies. The first three provide information about infant understanding of communication and language, and determine how well the infant is communicating by using speech sounds, gestures, and language with others. The last instrument uses parent report to determine the range and depth of the infant's vocabulary development.

### **Early Childhood**

Early childhood extends from approximately 3 to 5 years of age. It encompasses the "magic" years of language development, so called because this is the single most dramatic period of language growth in the life span. Many children who receive speech-language therapy are first identified during this time of life. They are referred for assessment by physicians, who may use instruments such as the Denver Developmental Screening Test to identify concerns; by parents who do not think their child speaks enough or does not speak clearly; and by preschool educators who are concerned about language comprehension, attention, and other skills essential in the learning environment.

For assessment, children may be referred to early childhood programs, free-standing clinics, private practitioners, or university training centers. Regardless of setting, the formal and informal assessment tools used to determine the adequacy of language development will be similar.

Formal assessment usually involves the use of standardized tests, and provides a full range of normative scores. Some common assessment instruments are the Preschool Language Scale, Clinical Evaluation of Language Fundamentals–Preschool, Peabody Picture Vocabulary Test (PPVT), and Expressive Vocabulary Test (EVT). These tests cover a range of language skills. The PPVT and EVT are both vocabulary tests normed on the same cohort, which allow for comparisons between receptive and expressive skills. Vocabulary tests are also embedded in the other instruments as a part of the battery. Other assessment domains include the understanding and production of *grammar* (the way words are combined to make sentences), *morphology* (the way word parts are used, such as prefixes and suffixes), *semantics* (how words and phrases create meaning), and *pragmatics* (awareness of

others as having unique beliefs, desires, and mental states, and the social use of language).

Informal testing consists of observation, recording a sample of the child using language during play with a peer or family member, and charting communication patterns. Informal testing by the SLP provides a cross-check on the standardized test results, since some children may do poorly on the more structured testing yet have adequate developmental language skills. The results of informal testing are reported descriptively and as age or developmental criteria comparisons. While this information may not be as easy to use as standardized test results, it is often better understood by parents and captures the everyday issues that resulted in the referral for evaluation.

### **School Age**

It is assumed that children are developmentally ready to learn when they go to school. Language is a pivotal developmental skill that is used and further developed in classrooms. It also serves as the basis for reading and writing. Some children will continue the treatment begun in early childhood. Others may have been discharged from language therapy but need further assessment because they are having difficulty attending to or understanding language-based classroom activities or learning to read and/or write. Additionally, some children with no history of language problems will exhibit these problems and be referred by teachers. Regardless of a child's history, the child's present status of language-for-learning skills must be assessed.

Assessment of school-aged children is usually based on norm-referenced tests unless a school has a response to intervention (RIP) protocol in place. When an RIP action plan is activated, extra assistance is provided to the child. If the child responds, a full evaluation is not recommended. Those children who continue to have difficulties even with this extra assistance are referred for assessment. In a full diagnostic workup, developmental language skills will be checked, but the emphasis will be on language-for-learning. Some of the most frequently used standardized tests include the CELF, PPVT, and EVT cited earlier, as well as the Illinois Test of Psychological Abilities and Woodcock Language Proficiency Battery. In addition to developmental language skills, phonological awareness, reading, spelling, and writing skills are now assessed. The goal is to determine if there is an unresolved developmental language

difference (for children up through Grade 3) or if the developmental language skills are adequate but the child is having difficulty taking these fundamental skills to a new context and transforming them into different language modalities (i.e., text based). The results of these tests are norm-referenced scores.

Informal assessment is included in a full diagnostic workup. This usually focuses on conversation skills, storytelling, and other pragmatic language skills that are best assessed when an interactive context is established. Results from these procedures are reported descriptively.

## Adulthood

There are many diseases and conditions that can affect language functioning, speech, and communication in adulthood. Most problems are caused by some kind of neurological impairment. For young adults, language difficulties result most commonly from head trauma (e.g., a car accident, motorcycle accident, or bullet wound). As middle age approaches, there is increased risk of stroke or tumor, and these become even more likely as adults move into what are considered the older years. Some problems (such as stroke) are static; once the damage occurs there is no further loss of functioning. Other problems (such as Parkinson's disease or Alzheimer's disease) are progressive; impairment increases over time.

Language assessment in adults is critical for a number of reasons. First, the assessment results will contribute to a better differential diagnosis of the underlying condition or disorder. Second, assessment outcomes will be used to design a treatment program. Finally, test results will provide information that is critical to counseling the client and significant others about the nature of the specific language problems, the probable impact of these problems on daily functioning and quality of life, and the prognosis for change.

Language assessment for adults may be performed in a variety of settings, including acute care hospitals, rehabilitation facilities, freestanding clinics, and the client's home. Virtually all assessments include informal observations of the person's speech, language, and communication skills in everyday tasks and contexts. In some settings, because of time limitations, informal assessment may be the primary process used to identify the problem and develop treatment plans. However, there are a number of language assessment test batteries that can be used to examine all aspects of an adult's

language functioning. For adults with language problems following a stroke, the Western Aphasia Battery and Boston Diagnostic Aphasia Examination are examples of comprehensive batteries. Other tests evaluate language, but also examine other cognitive and perceptual skills impaired by neurological deficits. Examples might include the Ross Information Processing Assessment and the Cognitive Linguistic Quick Test. Still other tests focus on one small aspect of language functioning (e.g., reading, understanding of sentence-length materials, or naming).

## Importance

Speech, language, and communication are complex behaviors. It is important to obtain an accurate assessment of language skills, deficits, and potential to determine the best way to improve language functioning. In addition, since language is such an important tool in counseling, it is critical to understand the person's linguistic abilities and challenges and to make certain that support for communication is provided. Without language, children and adults cannot participate fully in the world around them.

---

## LEISURE

---

Society perceives activities such as woodworking, writing, and playing a sport differently when performed as a job than when performed as a hobby. This

anomaly led psychologists to question the nature of leisure. What is it that makes an activity “leisure,” and are the consequences of performing these activities as a job different from the consequences of performing these as leisure?

Psychologists began the systematic study of leisure in the early 1970s. Two works influenced psychologists’ study of leisure behavior. In his 1974 book *The Psychology of Leisure*, John Neulinger proposed that activities be distinguished based on the extent to which the activity was freely chosen and was motivated by a desire to receive *intrinsic rewards* (i.e., rewards that are unavoidable consequences of the act of participation). Leisure occurs when individuals freely chose intrinsically satisfying activities. Work occurs when individuals respond to behavioral constraints to achieve extrinsic rewards. Neulinger’s view that leisure is more than the mere absence of work opened the door to psychological investigations of the similarities and differences in leisure and work activities.

Howard E. A. Tinsley and Diane J. Tinsley’s 1986 theory of *transcendent leisure experiences* provided a more multifaceted paradigm for the study of leisure. The theory postulated four conditions that are necessary for an activity to be experienced as leisure: freedom of choice, intrinsic motivation, optimal arousal, and involvement. The theory identified seven attributes of leisure experiences and suggested that leisure experiences are necessary for physical health, mental health, and personal (psychological) growth.

### Attributes of Leisure Experience

Leisure experiences vary from intense, life-transforming experiences to routine experiences that occur on a daily basis. Psychologists have focused on the most intense experiences because the attributes of intense leisure experiences are more readily identifiable than in routine experiences.

Five theorists have shaped psychologists’ conceptions of leisure. Abraham Maslow’s theory of peak experiences is the earliest and most comprehensive theory. Tinsley and Tinsley’s transcendent leisure experiences theory was influenced by Maslow’s work, but it deals more directly with leisure behavior. Maslow and Tinsley and Tinsley believe the attributes of routine leisure experiences are the same as, but less intense than, the attributes of transcendent leisure experiences. Mihaly Csikszentmihalyi proposed a theory of flow experiences that formed the basis for Chester F. McDowell’s

theory of leisure consciousness. Kathleen D. Noble’s theory of transcendent religious and meditation experiences has the narrowest scope.

Several common themes are discernible in these theories. The strongest consensus exists for the following attributes of leisure experiences:

- *Unity.* The individual and the experience become integrated and participants report a sense of unification with the world.
- *Absorption.* Participants focus exclusively on the activity and lose self-awareness.
- *Enriched perception.* Continued participation across time leads to a greater awareness of the nuances and complexities of the experience.
- *Positive outcome.* Leisure experiences provide a desirable way of truth finding that can lead to insights into universal truths.
- *Passive awareness.* Participants relinquish their control and allow the experience to unfold.
- *Loss of inhibition.* Participants feel confident, expressive, and daring; anxiety, defensiveness, restraint, and self-criticism are set aside.
- *Perceptual distortion.* Participants lose track of time and space.
- *Feelings of freedom.* Participants feel free and unconstrained by rules.
- *Intrinsic motivation.* Participants gain enjoyment from the mere act of participating in the activity.

### Causes of Leisure Experience

According to transcendent leisure experiences theory, freedom of choice, intrinsic motivation, optimal arousal, and psychological commitment are necessary prerequisites for an individual to experience leisure.

#### *Freedom of Choice*

Social psychologists refer to freedom of choice as the *illusion of control* because the individual’s subjective interpretation of the situation determines how the experience will be perceived. For example, individuals may perceive themselves as freely choosing to engage in behaviors that appear to others to be the result of external constraints. Leisure, developmental, and motivational psychology all view freedom of choice or the illusion of control as an expression of two of the most powerful motivations underlying human behavior: the desires for personal autonomy and for competence.

The illusion of control is important for maintaining mental health and successful functioning.

Threatening an individual's sense of freedom generates psychological reactance. *Reactance* is an aversive feeling that increases the attractiveness of the threatened freedom, stimulates aggressive feelings, and motivates the person to undertake action to regain the lost freedom. An individual's willingness to substitute one leisure activity for another is inversely related to the amount of external pressure to make the switch.

Research supports the position that freedom of choice is related to the perception of an activity as leisure. In one study, for example, leisure activities were regarded as voluntary approximately 40% of the time, whereas paid employment was seen as voluntary 5% of the time.

### ***Intrinsic Motivation***

Intrinsic motivation refers to the desire for rewards that are unavoidable consequences of the act of participation. For example, an individual who desires social contact would find visiting with close friends to be intrinsically rewarding because the very act itself involves social contacts. Extrinsic motivation refers to the desire for rewards that are not unavoidable consequences of performing the activity. Common extrinsic motivations include external coercion (e.g., work deadlines and imposed goals), the desire to avoid negative outcomes (e.g., criticism), and the desire for rewards such as money, grades, and recognition. From 40% to 65% of study participants described leisure activities as intrinsically motivated, but fewer than 5% described paid employment as intrinsically motivated.

Providing extrinsic rewards for intrinsically rewarding activities can destroy intrinsic motivation if the extrinsic rewards become too salient. Mark R. Lepper, David Greene, and Richard E. Nisbett demonstrated this effect in 1973. Preschool children who originally chose to play with colorful felt-tip markers were much less willing to play with the markers after an intervening time in which they had been promised and subsequently given a reward for playing with the markers. For this reason, parents should not provide extrinsic rewards to encourage their children to participate in activities that are intrinsically enjoyable.

### ***Optimal Arousal***

Walter B. Cannon observed in 1932 that all living organisms have a natural tendency to maintain a state

of internal balance or equilibrium. He called this tendency *homeostasis*. For the most part, homeostasis is maintained automatically. For example, we breathe without having to think about how much oxygen we need. In 1954, Henry W. Nissen extended this concept to include the cognitive functioning of the brain. He reasoned that there is an optimal level of cognitive stimulation (i.e., *optimal arousal*) that is maximally satisfying to the brain. Individual differences in sensation seeking, curiosity, and exploratory behavior are expressions of individual differences in optimal arousal level.

Wilhelm Wundt's general law of hedonic tone provides an explanation of the mechanisms underlying optimal arousal. He theorized that every stimulus has both a pleasant and an unpleasant effect. As the strength of a weak stimulus increases, the strength of its pleasantness component increases more rapidly than the strength of its unpleasantness component. Therefore, the stimulus is perceived as more and more pleasant. However, the pleasantness component reaches its maximum level while the unpleasantness component is still relatively weak. Once the pleasantness component has reached its maximum, further increases in the intensity of the stimulus increase only the strength of the unpleasantness component. That explains why increases in the intensity of a stimulus (e.g., adding salt to a bland dish) results in more pleasant sensations up to a point, after which further increases make the sensation less pleasant.

Daniel Berlyne, Marvin Zuckerman, and Charles Spielberger all proposed dual process explanations of optimal arousal. For example, Spielberger proposed that curiosity and exploratory behavior result from the simultaneous influence of curiosity and anxiety. Initially, increases in the strangeness, novelty, or complexity of an experience are pleasant (i.e., they increase curiosity or exploratory behavior). Pleasure is optimal when strong feelings of curiosity are accompanied by mild feelings of anxiety. As the stimulus becomes stronger, however, the salience of its negative component (i.e., anxiety) increases and the pleasantness of the experience decreases.

The effects of optimal arousal are difficult to investigate because many factors influence the level that an individual will regard as optimal. For example, breadth of interest—the tendency to seek varied, changing, and novel stimuli from a variety of sources—is an enduring personality trait. Some people have broad interests, while others have a limited range of interests. Other personal factors that influence the stimulus intensity an

individual will find optimally arousing include *curiosity* (satisfied by novelty), *sensation seeking* (satisfied by risk or increased stimulus intensity), and *skill* (satisfied by challenge). Csikszentmihalyi's flow model, for example, postulates that optimal arousal (i.e., flow) occurs when there is a balance between the challenge of the activity and the skills of the individual. Individuals who differ in skill level will also differ in the level of challenge that will be optimally arousing.

Despite these difficulties, it is clear that optimal arousal occurs more frequently in leisure than in work activities. Across multiple studies, about 60% describe novelty as an attribute of their memorable leisure experiences, but only 2% mention novelty as an attribute of their memorable work experiences. In general, participants describe their memorable leisure experiences as novel and intrinsically rewarding, their common leisure experiences as relaxing and intrinsically rewarding, and their memorable work experiences as extrinsically rewarding.

### **Involvement**

In 1947, Muzafer Sherif and Hadley Cantril proposed the concept of psychological involvement to explain the process by which individuals relate their personal sense of identity to a social object (e.g., a sports fan's elation when a favorite team wins). Involvement is a psychological state of arousal, interest, or motivation that has personal relevance to the individual. The strength of involvement influences the extent to which a person will seek out and process information about an activity, expend time and energy pursuing the activity, and continue to pursue the activity across time. Involved individuals place a higher value on the long-term benefits of participation in the activity, are more willing to sacrifice in order to continue the activity, and are more willing to derogate alternative activities to make them seem worse than they are.

### **Constraints and Affordances**

Constraints are factors that limit or prevent participation in leisure. There are three general types of constraints. *Intrapersonal constraints* involve individual attributes (e.g., personality characteristics) and psychological states (e.g., a temporary depression or elation). Lack of interest in an activity or prior unpleasant experiences with the activity are examples of intrapersonal constraints. These constraints prevent the individual from forming the desire or intent to

participate in the activity (i.e., they prevent the formation of intrinsic motivation).

*Structural constraints* intervene between the formation of leisure preferences or intentions and actual participation. An individual may find it difficult to participate in a preferred activity because of health problems, the lack of time, or inadequate financial resources. *Interpersonal constraints* involve other people (e.g., family responsibilities or the absence of a leisure partner). Structural and intrapersonal constraints limit the individual's freedom of choice.

Leisure participation is not dependent on the absence of constraints but on the successful negotiation of constraints. Furthermore, *affordances* (i.e., factors that facilitate leisure participation) influence participation. At present, leisure psychologists know little about the strategies used to negotiate constraints or the dynamic interactions between constraints and affordances. Integration of these constructs into a more comprehensive psychosocial model of leisure behavior is needed.

### **Benefits of Leisure Experience**

A benefit is a beneficial change or the maintenance of a desirable situation. Psychologists have examined a wide variety of potential benefits of leisure, including physiological and physical health benefits, mental health benefits, social benefits, economic benefits, environmental benefits, and benefits to the community.

Both individuals and social groups obtain benefits from leisure. Individuals obtain benefits such as increased life satisfaction, but this outcome also may contribute to an improvement in the morale of a family, a classroom, or a community. Social groups may receive direct benefits, such as when vandalism is reduced or community pride increases as a result of a leisure program.

Leisure activities provide 11 psychosocial benefits. In order of importance, they are:

- *Exertion.* Activities high on exertion emphasize vigorous physical activity; those low on this dimension offer relaxation and stress reduction.
- *Affiliation.* Activities high on affiliation provide opportunities to be with other people; activities low on affiliation satisfy the need to be alone and enjoy solitude. The importance of this benefit and nurturance (see below) are consistent with motivation theorists' conclusion that relatedness is one of the primary intrinsic motives.

- *Enhancement.* Activities satisfying the need for enhancement give individuals an opportunity to use their talents and develop their skills; activities low on enhancement provide little opportunity for personal development. This and the next benefit are consistent with motivation theorists' conclusion that competence is an important intrinsic motive.
- *Self-expression.* Activities high on self-expression emphasize variety and the flexibility to try unique approaches and ideas. Activities low on self-expression provide an opportunity to follow a familiar, comfortable routine.
- *Nurturance.* Like affiliation, nurturing activities offer a chance to be with and enjoy the company of others, but they also provide opportunities to support, encourage, and help others. Activities low on nurturance satisfy individuals' needs to pursue their own self-interests.
- *Compensation.* Activities high on compensation provide an opportunity to experience things that are missing from one's job or other routine activities; activities low on compensation provide pleasures similar to those obtained from other aspects of one's daily routine.
- *Sensibility.* Activities high on sensibility provide intellectual and artistic stimulation while those low on sensibility provide opportunities to reduce cognitive demands.
- *Conscientiousness.* Leisure activities high on conscientiousness emphasize responsible behavior and personal restraint; activities low on conscientiousness allow individuals to escape feelings of obligation and to focus on pleasant aspects of the present situation.
- *Status.* Activities high on status provide opportunities to receive attention, influence others, and feel important; those low on status allow individuals to avoid attention and the obligations of leadership.
- *Challenge.* Activities high on challenge emphasize personal skill and high levels of performance; activities low on challenge emphasize process more than outcome.
- *Hedonism.* Activities high on hedonism provide immediate pleasure without the need for long-term planning or commitment. Activities low on hedonism typically involve long-term goals.

### Applications of Leisure Psychology to Counseling

In the 1970s, Robert T. Overs and his associates at the Curative Workshop of Milwaukee developed an innovative leisure counseling program to address the needs of older persons and clients with disabilities. In

addition, several practitioners in the United States began to specialize in leisure counseling. Despite the encouraging results reported by these pioneers, however, mainstream counseling psychology has given scant attention to leisure.

### Future Directions

Almost everyone experiences leisure in some form, and almost everyone enjoys and values leisure, but leisure is presently an understudied aspect of life. Nevertheless, leisure behavior provides an amazingly fertile applied laboratory within which to study phenomena of interest to cognitive, social, motivation, human factors, vocational, and counseling psychologists. The growing interest in developing a positive psychology of the healthy personality may direct increased attention to leisure.

## LIFE TRANSITIONS

---

Life transitions may be defined as significant changes within the life course. According to the life course perspective, lives are composed of multiple, interrelated developmental *trajectories*. For example, a life course includes personal relationship trajectories, an educational trajectory, an employment trajectory, and physical health trajectories, among others. These trajectories are marked or accentuated by significant life transitions, with transitions in one trajectory often necessitating or involving transitions in another. The transition to adulthood may involve a residential transition from the family of origin to independent residence, graduation from high school and enrollment in some form of higher education or entry into the workforce, and significant relationship transitions as individuals move away from old friends and form new connections. The implications of life transitions, from a counseling perspective, vary dramatically by historical period, socioeconomic status, gender, race and ethnicity, as well as by individual factors such as personality, coping styles, social support networks, and other resources.

### Life Course Transitions

A traditional developmental perspective describes developmental tasks to be completed at each stage or transition in life. For instance, a Western developmental perspective might define the transition to adulthood as involving further establishment of personal identity, and increasing social and economic independence from parents. A life course perspective acknowledges the developmental uniqueness of transitions, but emphasizes the embedding of transitions within social contexts and historic and temporal processes. Thus, the meaning of a given transition, and individuals' ease in traversing it, depends on the social contexts within which it occurs. Similarly, the effects of social contexts on individuals depend on the stage or transition in the life course during which they occur. For example, research on the psychological and socioeconomic effects of military experiences during World War II found that effects depended on whether entry into the military occurred in early or later adulthood. For those entering the military right out of high school and before they had invested heavily in their careers, military service often resulted in positive socioeconomic outcomes in later adulthood, as it

provided training and work experiences, educational, health, and financial benefits, as well as a much improved economy upon returning home. In contrast, for those entering the military in their early 30s, military experience represented a major interruption of careers and family lives, resulting in significant setbacks upon returning home.

An important distinction is whether transitions occur at normative times and in normative sequences. Life course theory posits that life transitions are age graded, meaning that they typically occur within a given age range, and in a normative sequence. Transitions that occur at unusual ages (i.e., "off time"), or out of sequence, may be particularly difficult. The loss of a parent, for example, although never insignificant, has been found to have very different consequences if it occurs early in life (e.g., during childhood) or at a more normative age in later midlife. In addition to the timing of transitions, their duration is also of consequence. Research on the effects of poverty for children, for example, finds that short spells of poverty are less detrimental than prolonged exposures to economic hardship.

Contrary to developmental perspectives that emphasize continuity and the linear unfolding of human development over time, life course theory emphasizes discontinuity and nonlinearity. For example, research into the effects of job loss and other economic strains during the Great Depression found that economic conditions interacted with personality characteristics. Men with a propensity for aggression became even more aggressive in response to these challenges, and this accentuation of personal characteristics continued across the life course. Perhaps more interesting, however, are how later life transitions may represent turning points within the life course. Research on deviance across the life course has observed an apparent paradox. When viewed retrospectively, nearly all criminals are observed to have had delinquent pasts. When viewed prospectively (i.e., forward in time), in contrast, few juvenile delinquents go on to commit crimes as adults. One reason for the change is that most delinquents are drawn away from deviance through later positive life transitions, such as obtaining stable jobs or entering good marriages. In part, this growing out of delinquency is consistent with a pattern known as *adolescent limited delinquency*. Other research on turning points emphasizes the social psychological and symbolic nature of changes in identities that enable one to take advantage of these potential resources in adulthood.

Life course theory also emphasizes that individuals' transition experiences are inextricably linked to the lives of their significant others (e.g., spouses, partners, children, extended family members, friends, and other social networks). Thus, the effect of a transition is often moderated by the nature and extent of these social connections. For instance, research has found that undesirable economic transitions, such as loss of a job or loss of a family farm, affect parents, but also "spillover" to have detrimental consequences for children. Some research on gender differences in stress has found women to be more exposed to undesirable life events through their more extensive social support networks.

### The Stress Process and Transitions

The stress process model offers additional insights into the potential effects of life transitions. Most broadly, the stress model predicts that undesirable life events (e.g., job loss, death of spouse) produce stress and may result in diminished psychological or physical well-being. Even desirable transitional events, such as the birth of a child or receiving a job promotion, require adaptations that may produce stress. The type or nature of a given life event is critical to understanding its potential consequences. An important distinction within the stress literature is whether a given life event or transition is acute or part of a more chronic pattern of stressors. By definition, *acute stressors* are of short duration. They also tend to be more randomly distributed within the population, and to have more limited and short-term consequences. *Chronic stressors* tend to be associated with socioeconomic and other (race and ethnicity, gender) disadvantages, and represent recurrent problems that may accumulate over the life course and result in serious outcomes (e.g., increased morbidity or mortality). For example, chronic stressors (e.g., unemployment, food insecurity, exposure to environmental hazards) and poor quality social services (e.g., schools, health care) associated with low socioeconomic and minority status are thought to produce a premature weathering of the body and increased risks of morbidity and mortality. Life events that are out of individuals' control, are unexpected, and/or threaten salient personal identities are also found to be more stressful. For example, research has found job or economic-oriented life events to be more detrimental to men's well-being than to women's, as they threaten men's identities as family economic providers. Women, in contrast, may

be more influenced by undesirable life events within the family.

The stress literature also focuses attention on personal and social resources that individuals may draw upon to buffer the effects of transitional life events on well-being. Personal resources often associated with positive outcomes include self-esteem and self-efficacy. An individual's repertoire of coping strategies may also moderate the consequences of life transitions. Persons with more active coping or problem-solving styles are often better able to deal with stressors than those who respond passively or by ignoring the problem. Research also finds that the way individuals appraise the causes of life events (i.e., causal attributions) influences outcomes. For instance, life events that can be attributable to external causes (e.g., job loss during the Great Depression) are less likely to result in negative psychological outcomes than those that are attributed to individual deficiencies. Studies of job losses have found that the more people are able to make lateral social comparisons to others in similar situations, and/or positive social comparisons to those worse off, the better they are able to cope with their own stressors. Research similarly finds that the degree to which the external community attributes life events to the person, versus external causes, influences the amount of social stigma people experience. The material and economic resources at individuals' disposal are of obvious potential benefit for dealing with stressful life transitions. Relating closely to the life course concept of linked lives is the concept of social support. Perceived and actual social support (e.g., from spouses, external family, and social networks) is found to both directly influence well-being and to buffer against the negative effects of undesirable life events.

The life course and social stress literatures offer insights into understanding those who are best able to adapt to life transitions and other undesirable events. A variety of studies identify variables associated with *resilient* individuals (i.e., those able to beat the odds), including individual or social-psychological characteristics such as planfulness, self-efficacy, self-esteem, and intelligence; and social and socioeconomic resources such as community involvement, social support, human and financial capital, and high-quality public institutions and services. These perspectives also highlight the importance of considering how individuals and families actively adapt to their environments and transitional demands. In the study of families living in poor and/or dangerous neighborhoods, researchers have

found that successful parents employ a variety of tactics to minimize youth's exposure to community risks. Examples include "lock-ins," early curfews, family chaperonage, restrictions on places children are allowed to go, and tight control over relationships with peers. Such practices might be characterized as too restrictive or "authoritarian" within lower-risk contexts, but within stressful environments, they appear to be positively adaptive.

### Childhood Transitions

One of the first major transitions in life is the transition from home to formal schooling. Rather than a discrete transition, however, entry into formal schooling may include transitions from home to day care, from day care to prekindergarten (pre-K) programs, and from pre-K programs to kindergarten. Transitions from kindergarten to first grade, and subsequent grade transitions, must also be considered because of their unique developmental and social circumstances. Given associations between later academic difficulties and performance during the first several years of schooling, research and policymakers have focused on factors associated with school readiness, and interventions such as the Head Start program and other pre-K experiences. In addition to cognitive readiness, a student's social and behavioral competencies are also critical. Entry into elementary school involves a considerable change in social context, as kindergartens and first grades are typically larger than preschool or day care arrangements, and involve a more rigid set of behavioral regulations. Most research indicates that positive relationships between children and adults (both teachers and parents) are critical to fostering readiness.

Other research has focused on the yearly transitions from school back to families and neighborhoods during summer breaks. Though children start the school year with varying abilities, research has shown that all children make gains at about the same rate over the school year. However, research has shown that educational inequality increases during the summer. It is believed that the relative lack of resources available within the families and communities of poor and minority children explain these growing disparities over the summer.

A particularly significant maturational transition during adolescence is puberty. Early pubertal development is potentially problematic for both males and females, as it is associated with early sexual activity and increased

delinquency. Among boys, early pubertal development predicts both violent and nonviolent delinquency, likely due to its association with greater access to older peers. Early pubertal development among females is also associated with earlier sexual activity and greater exposure to intimate partner violence. Moreover, greater exposure to intimate partner violence may explain changing gender differences in psychological well-being during this period. Prior to puberty, males tend to have higher depression than females. This gender difference switches during puberty, with females developing higher rates of depression. This disparity is found to persist across much of adulthood. A related important issue for females is perceived body image. Negative perceived body image during adolescence has also been found to account for the higher depression and lower self-esteem of females relative to males.

Transitions from elementary school to middle school and from middle school to high school have also been found to be challenging. Many studies have observed setbacks during these transitions in psychological well-being and academic competence, including diminished perceptions of ability and loss of intrinsic motivations for learning. These transitions are thought to be difficult for several reasons, including ongoing pubertal development, the need to renegotiate peer relations within more diverse (e.g., in terms of ages and social statuses) student bodies, and the increasing competitiveness and stratification of schooling.

Transitions associated with family moves during childhood and adolescence may present challenges due to their disruption of friendship and other social networks. Research has found, however, that supportive parents may buffer youth against the negative effects of family mobility. The effects of family migration also vary as a function of social class and the impetus for moves. Moves associated with upward social mobility are likely to be less detrimental than are those associated with job losses, or that are necessitated by other undesirable life events. Though people's stability in their community is generally found to be associated with positive outcomes, inability to move away from poor and dangerous neighborhoods may be associated with restricted access to resources and ongoing experiences of discrimination.

### The Transition to Adulthood

Perhaps most examined is the transition to adulthood, which typically involves the multiple transitions of

moving away from the family of origin, transitions to higher education and/or employment, and the formation of new family and other significant relationships. Transitions to higher education are now quite widespread, with nearly 70% of high school graduates continuing on to college as of 2005. Not surprisingly, this transition varies significantly across subgroups of the population, with women outpacing men, and Asian and White young adults more likely to be enrolled than African Americans and Latinos/as. Of increasing importance in the transition to higher education are community colleges and other 2-year institutions. Community colleges are particularly appealing to those who have traditionally been unable to pursue higher education, whether due to limited economic resources, poorer academic performance, or other risk factors. Graduate and professional degree programs have also increased in importance, further extending the transition to adulthood and delaying, for many, transitions to marriage and childbearing.

For disadvantaged youth, the transition to adulthood is becoming more perilous. Exposure to violence in poor neighborhoods and schools has been identified as a significant risk factor for poor psychological, social, and behavioral development (e.g., posttraumatic stress disorder, aggression, depression). Exposure to violence undermines youth's sense of control, frustrates learning, and may lead to a foreshortened adolescence. Exposure to street and intimate partner violence has been linked to a variety of "early exits" to adulthood, including dropping out of high school, running away from home, teen pregnancy, and suicidal thoughts. Another significant risk within the lives of disadvantaged young men is incarceration. Increasingly punitive federal and state policies and increased funding for police and penitentiary facilities over the past several decades have resulted in a tremendous growth of the incarcerated population. Most affected by this change are low-education minority men, for whom incarceration is now a nearly expected stage in the life course. For example, nearly 60% of African American males without a high school diploma will have spent some time in prison by their early 30s. For those who have been convicted of criminal offenses, the transition back into the community has also become more difficult due to increased surveillance and monitoring within the parole system, and to limitations placed on their rights to public services, employment and, in some cases, citizenship. The "collateral consequences" of incarceration to relationships between incarcerated

men and their spouses and partners, children, and communities are beginning to receive increased research and policy attention. Though not widespread, comprehensive reunification and fatherhood programs within prisons and the community offer some promise for easing this transition.

Family transitions during early adulthood are becoming both more delayed and diverse. Numerous trends have affected family transitions over the past half century, including delayed age of marriage, increased rates of nonmarital fertility and single parent households, and increased cohabitation. Also contributing to fewer married households were rising divorce rates during the 1960s and '70s, which leveled off and have declined somewhat since the early 1980s. Current projections of the likelihood of experiencing the transition to divorce vary based on assumptions about future demographic conditions. Nonetheless, between 43% and 50% of first marriages are likely to end in divorce within 15 years. These divorce rates vary considerably across subgroups, with women marrying at young ages considerably more likely to divorce than those marrying at later ages. Cohabitation prior to marriage is now the norm, but is also less likely to lead to marriage than in the past, particularly among low-income and minority couples. One very positive trend in recent years is a decline in teenage fertility, particularly among African American youth.

Policymakers have increasingly paid attention to these trends due to the mounting evidence that living in married couple families (i.e., versus single parent families) is associated with a wide range of socioeconomic, psychological, and physical health outcomes. Welfare reform, child support enforcement, and more recent marriage promotion and father involvement initiatives have each sought to change incentives related to marriage and nonmarital fertility. Critics, however, counter that marriage promotion among disadvantaged couples may not make economic sense due to the poor economic prospects of men, and may expose women and children to abuse and other risk factors in the lives of disadvantaged men. Other researchers point out that divorce may result in positive outcomes when it alleviates chronic stress or abuse within the family. As more fathers live apart from their children, researchers have sought to identify factors associated with positive outcomes for children. Fathers able to retain emotional closeness to their children and who actively engage in authoritative parenting have been found to be most successful.

The transition to parenthood is a life-changing process. Previous research finds, particularly in the case of a first birth, that the transition to parenthood frequently produces stress for the individual parents and the couple's relationships. As with other transitions, the nature and degree of consequences depends on personal characteristics, individual and family adaptations, timing, and other contextual resources upon which parents may draw.

### Midlife Transitions and Beyond

Perhaps the best-known concept associated with middle adulthood is the *midlife crisis*. The term usually refers to men's lives and disappointments associated with transitions at work or within the family. Although surveys suggest that many adults expect to go through a midlife crisis at some time, it is perhaps more constructive to discuss the multiple transitions that men and women may face during an increasingly prolonged middle adulthood. Midlife has become both longer and more varied, due to improvements in health care and increased longevity, as well as changes in the nature of careers.

The notion of a single career, pursued within a single company, is a thing of the past, and was a construct that applied mostly to middle- and upper-class White men rather than all workers. It has been replaced for many by careers marked by employment for multiple companies, of mid-career "retooling" (going back to school), and significant career changes. Some have characterized this change as going from linear career trajectories to "negotiated" careers. Longitudinal studies of contemporary careers have identified several common career sequences, including the traditional stable, long-term tenure at a single firm, an upwardly mobile path with multiple transitions between jobs, intermittent careers with multiple entries and exits, and a stable part-time work trajectory. Men are more likely to follow the stable full-time and upwardly mobile paths, whereas women, especially those who are responsible for child or elder care, are more likely to pursue the intermittent and stable part-time routes.

Another common transition, particularly for women who have cut short their educations or careers due to family demands, is to go back to school and/or reenter the labor force. For those going back to school, being a nontraditional student can be both challenging and rewarding. In addition to concerns about fitting in with predominantly younger student

peers, many educational institutions are not organized to accommodate the schedules of older students. Older students are more likely to experience role conflicts or strains associated with juggling both educational and family responsibilities. More positively, however, other research points to the psychological benefits of holding multiple productive roles.

When children are economically independent enough to move out of the parental home, parents may transition into what is commonly called the *empty nest* phase. Far from a crisis, research has actually found that parents are happiest during this empty nest stage. For many, however, this empty nest phase is increasingly delayed or interrupted, as adult children may delay leaving home in order to pursue higher education, save up to buy their own house, or move back home following divorce or other unexpected life events. Within disadvantaged communities, and particularly in the case of single mother families, it is quite common to have multiple-generation households in which grandparents move in to provide social and economic support. The many productive roles that grandparents play within multiple generation households are receiving increased attention within both the research and policymaking communities. An adult's parents may also move into the household due to their own deteriorating health or for economic well-being. If the children are not yet out of the house, this situation is described as a "sandwich," in which adults are doubly burdened by caring for children and their dependent parents. Research into the effects of such multigenerational caregiving on depression suggests that the burden is higher for women, however, other research finds that having multiple productive roles confers positive psychological benefits as well.

Just as careers are becoming more varied, so too is the transition to retirement. Rather than a single transition point, retirement is better conceived of as an ongoing process. Work retirement may be gradual or intermittent, with transitions from full-time to part-time work, from private sector to self-employment, or the starting of second or third careers. For some, the transition begins many years prior to actually leaving the job, with the initiation of financial and lifestyle planning for retirement. The degree of planning for retirement, however, varies considerably by social class and other statuses. Those with unstable work histories, those at risk for job loss, and those with declining health are not able to plan for and retire on their own terms. As is true of work transitions in

general, retirement is a transition that often affects more than one person. An individual's retirement decision making is thus influenced by the career and health transitions of spouses or partners and perhaps other family members.

Due to increases in longevity, researchers are increasingly interested in factors associated with successful aging. Though definitions of *successful aging* (or aging well) vary considerably, most entail the absence of physical disabilities and a sense of life satisfaction. Much like the concept of resilience, being adaptive in the face of change and continued social engagement, including volunteering activities and participation in other productive roles, has been found to be associated with effective maintenance of psychological and physical health.

As life expectancies continue to rise, transitions to caregiving roles increase in both likelihood and duration. Interventions that provide information and respite to caregivers of persons with dementia or other Alzheimer's-related symptoms are receiving increased research attention. The transition to widowhood and its duration is also of increasing importance, particularly for women who have considerably longer life expectancies than do men. Though widowhood often triggers distress and poorer physical health, these associations may be buffered by social support from family, friends, and social networks, positive health habits, and the widows' continued participation in informal community activities.

Finally, researchers have begun to analyze the transition to death, and conceptualize positive transitions in terms of *dying well*. This is usually defined in terms of minimizing unnecessary pain and psychological

distress, facilitating contact between the individual and his or her most significant others, as well as satisfaction of surviving family members with the experience. The quality of physicians' care of patients, and patient and family members' efficacy and control over decision making, are contributing factors to a relatively positive experience. In the case of sudden deaths, however, many of these ideal factors may not be possible, and thus concern focuses on the psychological adjustment of survivors.

**MEANING, CREATION OF**

---

The creation of meaning is an essential and unique human function. Because meaning is not inherent in any action or event, it must be constructed in the mind of the participant or observer. The comprehension of past events provides the context for decision making for present and future behavior, as well as individuals' current sense of identity.

In the context of psychotherapy, creation of meaning is a change process in which clients construct the meaning of emotionally charged experiences by putting them into words. Creation of meaning involves perceptual, affective, and cognitive processes. It refers to the creation of language that helps clients know what they feel. It is the cognition of emotion. Because it functions as a critical within-therapy change event, creation of meaning is a key component of psychotherapy process research.

The following is an example of how creation of meaning can have far-reaching consequences for an individual's quality of life and level of success regarding age-appropriate developmental tasks: A 10-year-old boy suffered the loss of his mother when she died in a motor vehicle accident. He then interpreted his mother's death as an act of abandonment; he felt unsafe to form close emotional bonds with others,

particularly women. Twenty-five years later, he sought help from a psychologist for difficulties with committing to an intimate relationship with a partner. These issues created great distress for him and his partner. In the process of psychotherapy, it was discovered that he was still angry about his mother's death and that he held onto the belief that his mother's death was an act of abandonment, which led him not to allow himself to be emotionally attached to anyone. Psychotherapy proceeded to assist this client in achieving an awareness of multiple possible alternative meanings regarding his mother's sudden death (i.e., the motor vehicle accident was an accident, not his mother's deliberate act of leaving her young son), so that his range of choices of behaviors in relationships could become both expanded and conscious. For instance, he could choose women who are capable of forming a long-term intimate relationship, or he could learn to work through conflict instead of ending a relationship at the first sign of a problem.

Creation of meaning occurs in various psychological treatment approaches, such as cognitive-behavioral, experiential, and psychodynamic. It has been identified as a factor in the treatment of many psychological conditions or disorders (e.g., anxiety, depression, or posttraumatic stress disorder). The change processes involved in successful creation of meaning have been demonstrated in research to include both a cognitive and emotional dimension. Successful creation of meaning involves emotional, experiential exploration of the original event. In unsuccessful creation-of-meaning events, clients do not go through a process of exploring the origin of the belief or emotion in a highly experiential way. Therefore, emotion

and cognition need to be linked in designing therapeutic intervention to facilitate successful creation-of-meaning episodes.

## MEEHL, PAUL E. (1920–2003)

---

Paul E. Meehl was an intellect and Renaissance man who made enduring contributions in a diverse array of subject areas in psychology and beyond. In psychology, he was best known for his work in measurement, philosophy of science, biological bases of schizophrenia, statistics, and actuarial approaches to assessment and prediction. He also published in areas as diverse as political science, extrasensory perception, psychology and law, and religion.

Meehl was a relentless analyst, and his formidable critical faculties led him to some radical conclusions. His theory of *schizotaxia* (an inherited predisposition to schizophrenia-spectrum disorders) and his dislike of statistical significance tests as a basis for theoretical inferences have since gained wide acceptance. Other conclusions, such as his inclination to think that “there is something to telepathy” and his “skepticism about the received doctrine of organic evolution,” place him well outside the scientific mainstream and into the area of the “strictly taboo.” Meehl’s open-mindedness and probing intellect led to illuminating commentaries on virtually every subject that captured his interest. As a result, he probably authored or coauthored more “classic” conceptual papers (and

certainly in more diverse areas) than anyone in the history of psychology.

Perhaps his most influential contribution was to measurement theory. In a 1955 article coauthored with Lee J. Cronbach, Meehl revolutionized the process by which psychologists provide evidence for validity of measures used in research and practice. A major contribution of this article was the acknowledgment that, for most psychological measures, validity cannot be established by a straightforward comparison with a criterion, because normally no unambiguously valid criterion measure can be found. For example, one would like to validate a pencil-and-paper measure of depressive tendencies by showing that it differentiates depressed from nondepressed individuals—but there is no perfectly accurate method of differentiating these two groups to serve as a criterion measure. Cronbach and Meehl explored the implications of this revelation for measurement theory and laid the groundwork for a new approach to construct validation that is central to the postpositivist philosophy of science.

Meehl was a unique figure in psychology in another way. He was a first-rate philosophical and mathematical thinker who also identified strongly as a clinician. He practiced from a psychoanalytic orientation during his early professional decades, then incorporated perspectives from rational-emotive and brief psychodynamic therapies in his mature years. Psychologists who take the trouble to read his original papers on applied psychology (rather than relying on textbook or reviewer summaries) are likely to be pleasantly surprised by Meehl’s astute clinical “ear.” His writings reveal a keen appreciation for the virtues of clinical experience as a basis for theory and practice, and offer wise counsel on applied matters including training and certification, assessment and case conceptualization, and the role of science in informing the practice of psychology.

With a foot in each camp, Meehl was fascinated and sometimes surprised by the tensions between those psychologists who identified primarily as scientists and those who identified primarily as practitioners. Members of each faction were granted exalted social status in their respective domains—practitioners in their clinical settings, and scientists in the halls of academia—and each group could be sharply critical of the other, frequently employing unflattering emotion-driven characterizations. Meehl had little patience with such ad hominem attacks, and worked diligently to impress each camp with its limitations as

an exclusive basis for claims about valid theory or optimal practice in psychology.

### Limitations of Clinical Experience

As a clinician, Meehl was acutely aware of the power conferred on psychological practitioners by their social and institutional status. Psychologists are empowered to restrict individual liberty, to challenge and often change clients' construals of their life events, and even to influence law and social policy (via "expert testimony" in courtrooms and beyond). They are also, like all human beings, subject to perceptual and mnemonic biases that can cause them to draw faulty conclusions from their experiences. The dangers of overconfidence in "clinical wisdom" (particularly when the stakes are high) was the theme Meehl chose to return to in his Centennial Award address to the Society of Clinical Psychology (Division 12) of the American Psychological Association in 1997. He stated that clinicians must and should rely on their clinical experience for guidance in many professional contexts, but they should be honest with themselves and others about the limitations of this basis for knowledge claims and for behavior.

A case in point is the diagnostic and predictive decisions made by clinicians in a variety of clinical and legal contexts. Psychologists often rely on vague "clinical impressions" or on idiosyncratic synthesis of impressionistic and objective data in making such predictions. In 1954 Meehl compared such *clinical* (or impressionistic) approaches to prediction with a *statistical* (or *actuarial*) approach in which multiple pieces of information were combined using a (usually quite simple) mathematical formula. His scientific masterpiece, *Clinical Versus Statistical Prediction: A Theoretical Analysis and a Review of the Evidence* (and more recent reviews), demonstrated unequivocally that actuarial methods virtually always yield predictions as accurate as, and quite often more accurate than, less systematic approaches.

Meehl's conclusion—that idiosyncratic methods are more likely to impede than enhance predictive accuracy—has frequently been construed as a broad indictment of clinical judgment per se. This was not Meehl's interpretation of his findings. He set great store by expert clinical observations and noted that the actuarial models in some studies he reviewed incorporated at least some data derived from clinician judgments into the prediction algorithm. In fact, more of *Clinical Versus Statistical Prediction* was devoted to

defending clinicians' unique inferential activities than to criticizing their predictive abilities. Recent reviewers note that many of the studies reviewed by Meehl focused on prediction of broad life outcomes (e.g., Will this person be successful in the army? Will he or she become manic at some point in the future?). Meehl's cautious optimism regarding the validity of clinical judgment receives stronger empirical support when researchers examine moderate levels of inference typical of clinical practice (e.g., judgments that a patient is perfectionistic or sensitive to rejection).

In summary, Meehl believed that when no conclusive scientific data are available expert judgment is a necessary and sound basis for many clinical decisions. However, clinical wisdom, like other conclusions based on anecdotal evidence, is sure to lead to incorrect conclusions at least some of the time, and needs to be distinguished from scientific findings (or "credentialed knowledge"). Meehl believed that practitioners are acting irresponsibly and even unethically when they behave as if their expert opinions constitute credentialed knowledge.

### Limitations of Scientific Research

The scientific method permits a stronger basis for knowledge claims (including claims about effective practices) than expert judgment does. It involves systematic observations and measurements that are replicable in principle, thus reducing the contribution of motivated cognition and other biases to the findings on which conclusions will be based. This does not mean that researchers always follow the scientific conventions that maximize scientific validity (e.g., complete and accurate reporting of a priori hypotheses and research procedures). Nor does this mean that these conventions are rationally derived. Meehl recognized that the scientific method as currently practiced in psychology is imperfect, and with his colleague David Faust, developed a methodology (termed *cliometric metatheory*) for identifying scientific practices that could be demonstrated empirically to enhance the validity of disciplinary findings.

Meehl lamented the tendency of psychological researchers to be preoccupied with methodology but oblivious to the banality of many fashionable theories. In a 1978 article Meehl wrote, "I would take Freud's clinical observations over most people's *t* tests any time" (p. 817). Social sciences (to a much greater extent than physical sciences) are fraught with

conceptual complexities that researchers may be intellectually or methodologically ill equipped to handle, such as the stochastic (probabilistic) nature of causation and the necessity for open (evolving) concepts. Finally, Meehl believed psychologists' use of statistical significance testing as their primary method of theory testing was incompatible with postpositivist philosophy of science, and a chief culprit in the disappointingly "slow progress of soft psychology."

### Science and Practice

The implications of these critiques for the relation between science and practice are complex. Meehl was disheartened by what he saw as some clinicians' unwarranted faith in the authority of conclusions drawn from their own clinical experience, and their seeming disinterest in weighing evidence for alternative interpretations, even when these were grounded in scientific findings. As Meehl wrote in a 1987 essay, the "general scientific commitment not to be fooled and not to fool anybody else" (p. 9) is a desirable characteristic of clinicians as well as researchers.

Meehl acknowledged that few clinicians fulfill the scientist-practitioner aspiration of producing independent research (beyond the dissertation), and was supportive of scholar-practitioner (Psy.D.) training models that (ideally) train students as intelligent and critical consumers of research produced by others. Meehl was pessimistic about the value of most "soft" psychology research for either practice or theory, but identified five "noble intellectual traditions" he considered to have enduring value. Interestingly, three of these (psychometrics, applied learning theory, and behavior genetics) have emerged from scientific findings, whereas the other two (descriptive clinical psychiatry and psychodynamics) constitute practice-based knowledge.

---

## MEMORY, ASSESSMENT OF

---

Psychological research has shown that memory is not a unitary construct. Instead, memory consists of a coordinated collection of processes and abilities that work together to enable individuals' day-to-day functioning. Furthermore, one aspect of memory can be impaired while another remains intact. For that reason, psychologists do not rely on a single procedure for assessing memory. Many assessment measures exist, and commonly used assessment procedures contain multiple subcomponents, each aimed at assessing a particular type of memory. This entry reviews several types of memory and explains the different ways that they are assessed. At the end, it describes several full-length memory assessment measures.

### Types of Memory

#### *Immediate Memory*

Often termed *short-term memory*, immediate memory refers to the ability to hold information in

consciousness. This ability is demonstrated when one remembers a phone number long enough to make a call. Immediate memory is distinct from long-term memory, which is the ability to store information for later use, often over extremely long periods such as weeks, months, or years.

The earliest known assessment of immediate memory is the “memory span test” developed in 1887. In this test, a person is given a sequence of items (such as digits) to report in the order in which they were presented. The sequences begin small (e.g., 3–8–4) and are increased in size until they reach a length that consistently exceeds the person’s reporting capacity. The maximum length that a person can consistently report is the person’s memory span. A version of this task, the digit span task, is a component of many present-day memory assessment batteries such as the Wechsler scale (described below).

### **Working Memory**

Working memory refers to the ability to actively manipulate information in immediate memory. It is possible to think of immediate memory as a component of working memory. For example, one might hold a digit sequence in immediate memory while performing computations on it. Some psychologists make the distinction between simple memory span tasks (e.g., the digit span task) and complex memory span tasks. Simple memory span tasks are thought to tap a person’s immediate holding capacity, while complex memory span tasks are thought to tap a person’s higher-order abilities. A complex memory span task involves a simple retention component (e.g., holding a sequence of items in immediate memory) as well as active manipulation (e.g., performing arithmetic on numbers preceding each item in the sequence). Examples of complex span tasks include the reading span, in which people read lists of sentences and are told to remember the last word of each sentence. Later, they are told to repeat all of the “last” words in the right order.

There are verbal and visual forms of simple memory span, each involving different parts of the brain. Verbal memory span involves maintaining verbal information, such as sequences of letters or digits; visual memory span involves maintaining visual information, such as mental pictures. Visual analogs to simple verbal memory span tasks (e.g., the digit span task) include the Corsi Block Test, in which nine small cubes are arranged on a table and an experimenter taps

them at the rate of one a second. This is done several times, with different orders and different lengths of sequences. Participants are asked to point to the same blocks in the same order, and this is a measure of their visual memory span. The procedure can have several variations, in which more or fewer blocks are used, or placed in different positions.

### **Long-Term Episodic Memory**

*The Ability to Form New Memories.* Long-term episodic memory refers to the ability to store particular pieces of information in memory for access at a later time, and to retrieve that information after hours, days, months, or even years have passed. Long-term and immediate memory represent two different types of abilities. Some neuropsychological patients have impaired long-term memory but normal immediate memory span, while others show the opposite pattern.

Disruption to the ability to form lasting memories is associated with damage to the hippocampal, medial temporal, and diencephalic regions of the brain. It can also be associated with frontal lobe damage. Patients with such damage tend to show anterograde amnesia (a marked deficit in the ability to form new long-term memories). Anterograde amnesia can be revealed on memory tests that involve a delay between the encoding and retrieval of information (so that the person cannot rely on simple memory span). An example is a list-learning situation in which there is a delay between the study list and the memory test. Therefore, many memory assessment tests contain delayed list-learning tasks.

*The Ability to Access Established Memories.* Retrograde amnesia, a disruption of the ability to access already-formed long-term memories, can result from head injury. Memories that had been acquired during a short window of time prior to the head injury are commonly affected. However, access to more distant memories can be disrupted when a network of neurons that played a role in a well-established set of memories is damaged. Damage to this neural network can result in disruption of the ability to retrieve portions of one’s past. Tests for assessing retrograde amnesia often assess memory for commonly known information, such as memory for famous faces, famous events, or television shows from a particular era. An alternative assessment procedure involves

obtaining personal information from friends and relatives and then interviewing the amnesic to see what information is still retained.

### **Long-Term Semantic Memory**

Semantic memory refers to one's general knowledge base, such as that an apple is a fruit or a hammer is a tool. Whereas episodic memories are linked to particular events in time, semantic memories appear to have been abstracted away from the particular episodes that led to their formation. For example, many people know state capitals, but few remember the act of learning them. The relation of general knowledge to specific experiences remains a controversial topic, because it is not always easy to make the distinction between semantic and episodic memory.

Disorders of semantic memory, commonly termed *semantic dementia*, are often category specific. For example, there are documented cases of patients having impaired knowledge of plants and animals, but intact knowledge of objects. In other instances individuals' knowledge of objects is impaired, but their knowledge of plants and animals remains intact.

### **Prospective Memory**

Whereas the aforementioned types of memory involve the ability to access information from the past, prospective memory refers to the ability to remember to do things in the future. Time-based prospective memory involves remembering to perform a task at a particular time in the future (e.g., remembering to make a phone call at 3:00 p.m.). In contrast, event-based prospective memory involves remembering to do something in response to a particular event (e.g., remembering to say "happy birthday" to a colleague when encountering her at work). This distinction has been incorporated into some assessment tests. For example, the Cambridge Behaviour Prospective Memory Test (CBPMT) contains four time-based and four event-based tasks.

### **Skill Learning and Implicit Memory**

Implicit memory refers to memory performance on tasks that do not require awareness or conscious remembering. That is to say, people can demonstrate memory for an event without knowing it. An example would be if people received a list of words and later saw the stems of those words (such as *drain* and *dr\_\_\_*), then were

asked to complete the word stems. People often complete the stems to make words they saw earlier, instead of new words (such as *drop* to complete *dr\_\_\_*). This demonstrates memory for the word list, even though participants may not be aware of what guided the word choice. People with anterograde amnesia (the inability to form new memories) can typically still form implicit memories, or learn new skills without being aware of it. There have been examples of anterograde amnesics even learning to play chess after acquiring the disorder.

## **Common Assessment Measures**

The development of memory assessment measures has been driven not only by basic memory research but also by practical considerations. Tests cannot be too long, or patients may become fatigued or impatient. In addition, the abilities that the assessment measures should resemble those memory abilities that are relevant to a person's day-to-day functioning. Memory assessments generally contain normative data in their manuals for use in evaluation. However, scores on memory assessments should be interpreted in light of such considerations as the person's age, intelligence, and level of education. Also, depression can be a significant factor in reported memory problems. An important thing to keep in mind when interpreting scores on a memory assessment is that a wide range of responses can be considered normal, and a large number of variables can affect any one of the different types of memory. This section describes some commonly used memory assessment methods.

### **Questionnaire Methods**

Questionnaires provide a simple means of assessing a person's memory. A number of questionnaires have been developed for this purpose, many of which are aimed at assessing whether a person has memory problems that interfere with day-to-day functioning. Some examples are the Inventory of Memory Experiences, the Everyday Memory Questionnaire, and the Comprehensive Assessment of Prospective Memory (CAPM).

### **Memory Assessment Batteries**

Individuals with memory impairment are not always aware of their impairments and subjective reports by patients and their families are subject to biases. For those reasons, it may be preferable to assess memory by testing memory performance itself.

*The Wechsler Memory Scale—Third Edition (WMS—III).* The WMS—III is one of the most widely used memory assessment procedures. The WMS—III consists of eight primary indexes that describe immediate memory, general memory, and working memory in visual and auditory forms. Each index comprises several subtests. Including the optional subtests, there are 11 subtests in total. They are logical memory, verbal paired associates, letter-number sequencing, faces, family pictures, spatial span, information and orientation, word lists, mental control, digit span, and visual reproducing. It takes around 30 minutes to administer, with an extra 20 minutes for the optional subtests. The WMS—III is the third edition, with the original version first appearing in 1945. It is considered by many to be the best memory assessment available.

*Rivermead Behavioural Memory Test (RBMT).* This test was developed to assess the types of memory that are most relevant to day-to-day functioning. It includes subtests that assess name recall, remembering the locations of hidden objects, prospective memory, picture recognition, recall of a story (immediate and delayed), recognition of unfamiliar faces, recall of a route (immediate and delayed), and remembering a passage. The test requires approximately 25 minutes to administer, and scores on the test correlate well with the number of patient memory lapses observed in clinical settings. The RBMT has four alternative forms for use in longitudinal testing.

*Other Memory Assessment Measures.* Other commonly used memory assessment measures include the Recognition Memory Test (RMT) and the Memory Assessment Scale (MAS). The RMT takes approximately 15 minutes to administer and contains two subtests that assess recognition of words and recognition of faces. Each subtest involves presentation of a study list followed by a recognition test that requires the discrimination of studied and nonstudied items. The MAS contains 12 subtests: list learning, prose memory, list recall, verbal span, visual span, visual recognition, visual reproduction, names-faces, delayed recall, delayed prose memory, delayed visual recognition, and delayed names-faces recall. The MAS requires approximately an hour to administer.

### **Professional Expertise**

The memory assessment procedures described here, like all memory assessment procedures, require graduate-level or professional training to administer

and interpret. Most assessments come with manuals that contain extensive instructions on how to administer the test, as well as normative data for the interpretation of performance. Selecting the appropriate test for a given situation is a matter of the examiner's experience and personal preference.

### **Factors Influencing Assessment**

Memory research has influenced the development of present-day memory assessment techniques, but not all forms of memory are assessed in the commonly used batteries. For example, it is common to assess short-term memory span and delayed episodic memory ability. It is less common to assess implicit memory. Two factors drive such priorities. First, time is of the essence when administering tests. Second, therapists are most concerned with assessing the forms of memory that, when damaged, interfere most with the person's ability to continue in a career or resume daily living. When a person's memory skills have been impaired, psychologists consider how the person might capitalize on spared forms of memory for rehabilitation. For example, psychologists have been successful in training people with anterograde amnesia to use skills that draw upon implicit memory.

## **MENTAL STATUS EXAMINATION**

---

The Mental Status Examination (MSE) is an evaluation of a client's current overall functioning with emphasis

on his or her cognitive and emotional functioning. The MSE is a structured observational system of the client's behavior, emotions, and thoughts. The MSE is often confused with the Folstein Mini-Mental State Examination, which is a standardized screen for dementia. The MSE has several components, which generally cover the client's appearance, behavior, and attitude toward the examination, speech, affect and mood, thought process and content, sensory perception, and general cognitive functioning. Different clinicians use slightly different categories, but the goal of each approach is the same—to provide a clear and comprehensive description of a client's overall functioning.

Appearance includes a description of the client's body, movements, dress, and overall grooming. Speech includes a description of the client's rate and volume of speech as well as ability to articulate. Affect and mood includes both a statement of the client's self-report of feelings and the clinician's impressions of the stability, appropriateness, and range of the client's affect. A description of the client's thought process and content refers to the coherence of the client's thoughts and the presence of any dangerous or psychotic ideas. A sensory assessment includes vision and hearing problems and the presence of any illusions or hallucinations. Assessment of overall cognitive functioning includes the client's estimated intelligence, alertness, attention and concentration, memory, insight, and judgment.

The psychosocial history and the MSE provide the clinician with information about both the client's past and present functioning and provides the information needed to form a complete picture of the client's current condition. The MSE can be completed in a narrative or a checklist format. MSE checklists for children, adolescents, and adults allow the clinician to gather rich data in a thorough and efficient manner. Two examples of MSE checklists are Schinka's Mental Status Checklist for Adults and Dougherty and Schinka's Mental Status Checklist for Children. Choosing an MSE designed for children is particularly helpful because it adapts the general areas of observation to a child's developmental level.

## METAPHORS, USE OF

---

Metaphor is a form of figurative language, often described as facilitating the understanding of one thing in terms of another. In the comparison between two seemingly dissimilar concepts, the meaning of the first is carried over to help illuminate the second. Metaphors are valuable tools in the counseling process because they create structure, explain ideas, evoke emotion, and influence attitudes.

### Metaphor and Counseling

In counseling, metaphors may be generated by the counselor or the client.

Counselors use metaphors to interpret or clarify a client's experience, reflect feelings, organize previous topics, or explain a course of action. Some have argued that metaphor is an effective way to confront clients due to its indirect nature. Social psychologists have demonstrated that metaphor can be an effective tool in persuasion, which is in keeping with a social influence model of the counseling process. Novel metaphors can make an idea or topic more memorable to the client.

Clients may use metaphors to express emotions or experiences that they have no other way of describing. Using metaphors, clients can frame an idea in a way that they believe will be understood, integrating what is complex, and highlighting salient aspects of an experience. Indeed, some would argue that metaphors are the only way to fully express certain abstract and amorphous inner experiences.

## Working With Metaphors

A single metaphor can be as simple as three words, or involve an entire story. It may only arise at one point, or may be extended throughout the course of treatment. The metaphor can also be collaborative, with both counselor and client expanding and refining it over time. In a simple example, a client might describe a relationship this way: "It's like I'm the bank and all I'm doing is cashing checks." Over time, the counselor may ask if there are any deposits being made, and progress may be measured within the framework of the metaphor.

The use of a novel or exaggerated metaphor can often elicit strong visual images that help to make an issue more memorable. The oft used "When are we going to talk about the elephant in the room?" is a good example; the visual image helps convey the idea of importance. Metaphors may also be more effective when the content includes something of personal interest to the listener.

The frequency of metaphor use appears to vary across counselors, clients, and sessions, and there are individual differences in the ability to develop and comprehend metaphors. The aptness and salience of metaphors appears to be more important than how often they are used. It appears that metaphors that are

generated within the context of unique counseling relationships may be most effective.

Some authors have expressed concern about the vagueness of figurative language, and the possibility that it hinders true communication. Research involving the accuracy of client or therapist understanding of metaphors has not yielded any conclusive answers, but it would seem wise for counselors to be aware of these concerns.

## NARRATIVE THERAPY

---

Narrative therapy (NT) refers to a variety of approaches that focus on the role of language, particularly stories, in counseling. The central thesis of narrative therapy is that clients tell stories in therapy and these stories are useful in assessing and helping clients. Narrative therapy's broad explanatory power and useful therapeutic techniques have generated considerable interest among contemporary counseling psychologists.

### Purposes of Narratives

Narrative therapists maintain that people use stories to make sense of their life experiences. Stories form informal theories or maps of personal experiences and history. Narratives allow storage of large amounts of information, particularly information relevant to personal goals; they facilitate quick decision making; and they organize information about social interactions and experiences.

Narratives provide important information about the speaker's worldview, as illustrated by the following examples. One writer might say "Language is the data of counseling" to explain the importance of narratives in counseling. By that the writer means that much of the important information communicated between counselor and client takes the form of the connotations and denotations of spoken language. But that description also reveals something important about the writer; that is, that the writer tends to view his or her professional world through the role of a *researcher* who seeks to obtain and understand *data* related to counseling.

A more behaviorally oriented writer might say "Language is the behavior of counseling," while a theatrical writer might say "Language is the script of counseling." These descriptions convey different aspects of the potential role of language in counseling, but all are valid and all reveal something of the speaker's roles and worldview.

### Narrative Use in Different Counseling Approaches

All therapies pay attention to language to some degree. For example, rational emotive behavior therapy (REBT) practitioners listen for clients' use of words, such as *must* and *should*, because those words often indicate irrational beliefs (i.e., untrue thoughts) that lead to distress for the individual. For example, a client might say "I must get an A on this test!" An REBT counselor would challenge that statement and explore with the client what would happen if he or she did not receive an A on that particular test. Another example: A father might report "I'm frustrated because my children *always* disobey me," when in fact, most disobedience occurs when the children are physically tired. A solutions-focused counselor might help this client recognize this more complete description so that the client could begin to perceive his children differently.

### Narrative Use to Help Clients Change

Narrative therapists and their clients extract meaning from client stories, with the goals of helping clients understand themselves and change some aspect of their lives. *Deconstruction* is the process in which

therapists help clients become aware of the dominant story that guides their lives and to question its elements so that the story becomes just one possible view of the self. Other life events become more fully incorporated into the story and the client is placed as a more active protagonist in the story. For example, the student who reports that she “must get an A on a particular test” may also tell stories of other tests and courses in which she feels pressure to perform extremely well. However, she is also likely to be able to recall situations in which she did not perform extremely well and no catastrophic consequences occurred. The client may also relate instances when she felt relaxed while performing. Narrative therapists explore events such as these in an attempt to integrate an expanded account into the client’s dominant plot.

Because of the potential importance of emotion-related themes, many narrative therapists also pay particular attention to the affect described in client stories. Emotions are the glue that holds the story together. Some narrative therapists describe this work as similar to a corrective emotional experience in which clients reenact events in their stories. Research with single cases suggests that clients’ disclosures of emotionally charged personal narratives lay the foundation for subsequent change in counseling.

Considerable empirical support exists to support the benefits of finding meaning in narratives. Creating and finding meaning through exploration of personal narratives appears to regulate emotion as well as maintain and repair relationships. For example, in one investigation, college students wrote a description of a vivid memory and completed measures of personality adjustment and coping. The researchers examined the written narratives for the presence of statements that indicated the creation of meaning (e.g., those with beginnings such as “I learned that . . .” or “This experience taught me . . .”). The researchers found that moderate self-restraint, but not low or high self-restraint, was associated with greater numbers of memories related to insight and learning.

### **The Counseling Process in Narrative Therapy**

Exactly how this process of creating meaning and affective expression should proceed in counseling is less clear. The narrative counseling process often appears relatively unique to the particular client and

counselor working together. With each client the counselor finds the best method to overcome obstacles and facilitate client progress. For example, many clients tend to stay in storytelling while therapists attempt to focus them on internal states. With such clients the counseling process often involves weaving between talking about emotional personal narratives and efforts to find meaning in those narratives.

Other narrative therapists describe the counseling process as helping clients stay with and articulate their feelings. This permits key narrative elements to fully emerge and constrains previous habitual interpretations. More emotion is typically present in the beginning of storytelling and clients should not attempt to interpret their stories but just allow them to flow out. Finding meaning in narratives occurs later in the process. Thus, it appears that a successful counseling process involves the client fully exploring and experiencing a personal narrative and later making sense of (or drawing lessons from) the narrative’s events.

A similar pattern occurs when the change process involves *written* narratives. Investigations of the effects of writing about personal traumas typically involve a person writing about his or her deepest thoughts and feelings regarding a trauma for 15 to 30 minutes a day for 3 to 5 days. This procedure requires participants to create a written narrative of some incident, and the evidence suggests that it induces affect and meaning in ways that are very similar to traditional counseling.

Researcher Joshua M. Smyth’s recent meta-analysis (i.e., a statistical analysis of published research data) of 13 studies compared the written narrative procedure with some type of control group (typically another writing task, such as “Write about your plans for the day”). Writers in the narrative procedure typically reported an increase in short-term distress before later improvements became evident. The amount of short-term distress was unrelated to subsequent change. Analyses of word use patterns indicate that persons were more likely to benefit if their writing contained more positive emotion words, a moderate number of negative emotion words, and an increase in the number of causal and insight words from the beginning to the end of the narrative. These findings suggest that coping depends heavily on construction of a meaningful narrative about traumatic events and that successful therapy requires individuals to move from a focus on emotions and self to drawing lessons and meanings from the event(s).

## Future Directions

An approach to counseling that focuses on language appears to arrive, and eventually fade away, every few decades. In the 1970s and 1980s, neurolinguistic programming (NLP) was a popular therapy that heavily utilized storytelling and metaphors. However, many of its tenets did not receive research support or were not evaluated from a research perspective. Given the relatedness of NLP and contemporary approaches to narrative therapy, this is cause for skepticism about the efficacy of narrative therapy. The concern about the efficacy of narrative therapy is heightened by the fact that some contemporary narrative therapists appear disinterested in or openly antagonistic to research evaluations of their work. Nevertheless, process and outcome assessments of client narratives, such as the trauma writing-procedure research described above, appear to be potentially fruitful grounds for further investigation.

## NEUROPSYCHOLOGICAL FUNCTIONING

---

Neuropsychology is the study of brain-behavior relationships through objective, scientific methods. The main goal in neuropsychology is to understand how the brain produces and controls behavior and mental processes, including emotions, cognition, and consciousness. This goal is met by studying both healthy and damaged brain systems using objective measures to link biological and behavioral domains.

The goal of *clinical* neuropsychology is to study how cognitive skills such as memory, language, and attention change an individual's life as a result of brain injury, disease, or developmental process. The ultimate objective is the clinical application of that knowledge to human problems. Neuropsychological tests and methods are used to compare an individual's behavior to that of individuals with known brain dysfunction and to a normal control population. Psychologists draw inferences from the test data regarding what type of brain dysfunction may be present. From this point, realistic expectations for adjustment, remediation, and rehabilitation of behavior are made.

Neuropsychology is the fastest-growing subspecialty in psychology. Prior to 1975, neuropsychology was not considered a separate subspecialty, and was often part of clinical psychology, biopsychology, or neuroscience. Between 1975 and 1990, there was an increase in the clinical uses of neuropsychological information beyond the research laboratory, with an emphasis on creating test batteries that could be used to guide diagnosis and intervention with neurology patients. During this era, three professional organizations were founded (the International Neuropsychological Society, the National Academy of Neuropsychology, and Division 40 of the American Psychological Association, or APA), and several academic journals representing the discipline were established. In the years since 1990, neuropsychology has enjoyed increased acceptance in health care and forensic areas, but the economic changes (e.g., decreased reimbursement) that have affected health care in general also have affected clinical neuropsychology.

This entry outlines the main uses of neuropsychological assessment, and discusses the debate regarding the use of fixed versus flexible batteries. A typical neuropsychological evaluation is described. Tests are suggested to measure functioning in a variety of domains. Finally, the future of neuropsychology is addressed.

### **Uses of Neuropsychological Assessment**

Neuropsychological assessment is used for many purposes. Patients may be referred by a neurologists or general practitioner for an assessment as part of a diagnostic workup (e.g., for dementia) or to establish a baseline following an injury or illness. Neuropsychologists may be asked to complete an assessment for the purpose of evaluating competency or independence, or to make a recommendation about a patient returning to work or school.

School personnel may refer students to determine if a learning disorder or other developmental disorder exists, to specify subtype and prognosis of the disorder, and to recommend academic accommodations. Assessment may also be used to provide recommendations for psychosocial or family interventions. Information from the evaluation may help family members accept the patient's limitations and consider changes in the environment to accommodate any deficits.

Finally, neuropsychological assessment may be used to evaluate change over time. This information may be used to determine the course of changes and the prognosis for future functioning in cases involving traumatic brain injury or a progressive disease (e.g., certain dementias). Also, treatment efficacy (e.g., effect of medications or rehabilitation efforts) can be evaluated with repeated assessments.

### **Fixed Versus Flexible Batteries**

One controversial issue in neuropsychology is the use of fixed versus flexible test batteries. The most commonly used fixed battery of tests is the Halstead-Reitan Neuropsychological Battery (HRB). The HRB is a group of psychological tests that, taken together, are used by neuropsychologists to distinguish patients considered to have brain damage from patients with no known history of disease. The HRB uses an index of impairment to predict the presence of brain damage in patients. Test norms exist for a normal control

group and for patients with various types of brain damage. The HRB has stimulated a great deal of research in past years.

There are several advantages to using a fixed battery. Since a standard set of measures is used, the functioning of different patients can be compared. An evaluation is unlikely to overlook an important condition because all subjects are evaluated for all basic neuropsychological abilities. Fixed batteries are easy to teach, because the beginning student does not have to make decisions about test selection, and interpretation is objective and data driven. Finally, fixed batteries are useful for empirical studies and facilitate comparison across different research projects.

There are also disadvantages to fixed batteries. First, the purely empirical approach does not always lead to the most interpretable measures because it can be difficult to describe what the tests are measuring or to tie task performance to real-life situations. Fixed batteries tend to be unnecessarily long and tedious for some patients. This leads to noncompliance and discomfort, especially in older or more impaired patients. These batteries can be difficult to justify economically, which forces the use of technicians. Then the neuropsychologist loses the opportunity to directly observe the patient's behavior during the assessment.

Another approach is the use of a flexible battery (also referred to as the process or hypothesis approach). In this method, the neuropsychologist adapts each exam to the individual patient. Tests are selected based on hypotheses about the patient and available information, such as medical findings and history. Standard tests may be used, or tests may be altered to determine the nature of the deficit. Qualitative interpretations of test results and patient behavior play an important part in forming conclusions.

An advantage of the process approach is that it takes into account the individual nature of the patient's deficits, and adapts the exam to obtain more precise measurements of a cognitive ability. The exam can reduce assessment time by focusing on the most important areas and ignoring those that are not relevant for the patient's prognosis. Finally, the process approach emphasizes the way in which the patient fails or succeeds in a particular cognitive task. For example, if a patient is unable to answer a factual question, the process approach allows further investigation beyond the standardized test. The difficulty could be caused by an impairment of speech comprehension, expressive aphasia, or poor factual knowledge. By allowing the

patient to answer in a different form (e.g., multiple choice), the neuropsychologist obtains information that would have been missed using a purely standardized approach.

One disadvantage of the process approach is that the exam may selectively confirm an opinion because its content emphasizes what the neuropsychologist thinks is important. A deficit may be missed because an area was not considered relevant. This affects prognosis and rehabilitation since they rely on the brain functioning as a whole. Second, using tests that are not standardized for a clinical population can cause problems. Subjective interpretation of what a score might mean may be completely wrong. A test that measures one thing in a normal population may measure something different in a neuropsychological population. Finally, the process approach is more difficult to teach because few rules and procedures exist. Judgments made by the neuropsychologist often depend on extensive clinical experience, so the exam must be conducted by the neuropsychologist rather than a technician. This places limits on the time of the neuropsychologist.

A majority of neuropsychologists combine the fixed and process approaches in the form of a modified battery. They integrate data from a variety of sources (tests, medical findings, and developmental history), while taking into account the injury or disease process, personality, and other moderating variables that may affect test performance.

## Typical Neuropsychology Evaluation

### *History and Behavioral Observation*

A neuropsychological evaluation begins with taking a history of the patient beginning with demographic information, reason for referral, and the patient's chief complaint. Family history should include the state of health or the cause of death of parents, brothers, and sisters; history of familial diseases such as hypertension, stroke, or cancer; and history of cognitive or emotional disorders in the family. Social history should include use of drugs and alcohol, and reactions to life situations of stress and conflict.

A medical history begins with prenatal development and assesses several areas. It is important to assess whether the patient was a premature baby, whether any complications occurred during or after delivery, and history of childhood diseases, developmental problems, major illnesses, accidents, head

injuries, or loss of consciousness. Delays in the acquisition of motor, language, or intellectual skills are examined. When assessing for brain injury, details about the accident are gathered (e.g., when it occurred, loss of consciousness, hospitalization, and occurrence of posttraumatic amnesia).

An educational history is taken, including highest grade level achieved, academic performance, and general attitude toward education. Patients are asked if they ever received any special tutoring, were placed in any special classes, ever failed or had to repeat a grade, or had difficulties with any particular subjects. Vocational history should include the type of jobs held, the frequency of job changes, and any recent occupational problems.

Handedness is determined since it is an indicator of cerebral dominance, which can affect responses to neuropsychological assessments. It is usually sufficient to ask the patient which hand is dominant, but it may be necessary to obtain responses on a lateral dominance exam. Most of the population is right-handed, indicating left hemisphere dominance, but less than half of those who are left-handed are left hemisphere dominant.

Behavioral observations should go beyond physical description and include general appearance, personal hygiene, and noticeable physical defects (e.g., vision, hearing, and gait). In addition, it is important to be sensitive to other aspects of behavior including speech (speech difficulties, flow, appropriateness, and affect), posture, facial expression, eye contact, tics, and any unusual behaviors or involuntary movements.

### *General Intellectual Functioning*

Intellectual functions for adults are most frequently measured with the Wechsler Adult Intelligence Scale—Third Edition (WAIS-III). The WAIS-III consists of 14 subtests that are combined into three IQ scores and four index scores. Although the WAIS-III was not developed to be a neuropsychological instrument, several scores are helpful in forming hypotheses about a patient's presenting problem. The reliability and validity of all of the Wechsler scales have been well documented.

The Verbal Comprehension Index (VCI) is made up of three subtests: Vocabulary (vocabulary knowledge), Similarities (semantic information and abstract thinking), and Information (factual knowledge). Performance on the VCI is influenced by educational

history; it requires understanding words, drawing conceptual similarities, and knowledge of social situations. The Perceptual Organization Index (POI) is a measure of nonverbal abilities and novel problem solving. The POI comprises three subscales: Picture Completion (visual processing and attention to detail), Block Design (visual-motor ability, spatial processing, and problem solving), and Matrix Reasoning (visual processing and abstract reasoning skills in a multiple choice task). The POI assesses ability to examine a problem, use visuomotor and visuospatial skills, create solutions, and then test them.

The Working Memory Index (WMI) consists of the three subtests: Arithmetic (arithmetic abilities and working memory), Digit Span (encoding and verbal short-term memory in Digits Forward and working memory in Digits Backward), and Letter-Number Sequencing (working memory). Working memory is an executive function that is essential for cognitive flexibility and planning ability, as well as learning and self-monitoring. Working memory is an active process and is not the same as short-term memory, which is often viewed as a passive process. Finally, the Processing Speed Index (PSI) includes two subtests, Digit Symbol-Coding (visuomotor coordination and response speed) and Symbol Search (visual processing). The PSI assesses skills in focusing attention and quickly scanning and discriminating between visual information.

Two WAIS-III subtests are not used in computing any index scores, but they are used to calculate IQ scores and they provide information that is useful in neuropsychological assessment. The Picture Arrangement subtest measures visual processing and sequential thinking. The Comprehension subtest measures social knowledge and practical reasoning. Finally, Object Assembly is a completely optional subtest. Matrix Reasoning, which replaced Object Assembly in determining Performance IQ in the WAIS-III provides a purer measurement of perceptual organization because it does not measure speed of performance.

## **Attention**

Attention implies alertness to the world and can be broadly defined as the ability to attend to a stimulus. Four processes must be assessed when diagnosing attention-related disorders.

Encoding is the capacity to briefly hold information in mind while performing some cognitive operation on it. Encoding involves the sequential

registration and recall of information, and is related to listening comprehension. Encoding is typically measured by the WAIS-III Arithmetic and Digit Span (Digits Forward) subtests. Other tests used to measure encoding include the first trial of a list learning test, such as the California Verbal Learning Test, 2nd Edition (CVLT-II), discussed below in Learning and Memory. The interference trials of the CVLT-II can also be used as a measure of encoding. Other narrative tests for encoding include sentence repetition or story recall tests (e.g., the Wechsler Memory Scale—Third Edition [WMS-III] Logical Memory subtest).

Sustained attention is the capacity to stay on task for an appreciable interval, respond quickly to designated targets, and inhibit responses to nontargets. Inhibition is central to the concept of sustaining attention because attending to a stimulus implies inhibiting a response to other stimuli. Sustained attention is typically measured with a continuous performance test presented on a computer or other mechanical device, such as the Gordon Diagnostic System or the Connors' Continuous Performance Test II (CPT II).

Shift is the capacity to shift attentional focus in response to changing information. The Wisconsin Card Sort Technique (WCST), a good measure of abstract reasoning, concept generation, and perseverative responding, is the best measure of the ability to shift attention. The WCST requires patients to sort cards into categories according to color, form (shape), and number, using changing feedback from the examiner. Patients who have difficulty shifting will continue using the same category instead of using feedback to adjust their behavior.

The final component of attention is focus/execute, which is the capacity to concentrate attentional resources on a specific task (focus), screen out distracting stimuli, and respond appropriately and quickly (execute). Focus/execute is typically measured by tests such as the WAIS-III Coding and Symbol Search subtests, the Color-Word and Trail-Making subtests of the Delis-Kaplan Executive Function System (D-KEFS), and the Stroop Color and Word Test. These tests require persons to quickly make perceptual discriminations and a verbal or motor response.

## **Language**

Language functions comprise several cognitive abilities, including comprehension, speech, reading, writing, and spelling. Patients may experience a

variety of language difficulties. Dysarthria is a disorder of articulation that can result in slurring or mumbling. Dysprosody is an interruption of speech melody caused slowing and monotone voice. Apraxia is the inability to carry out movements of the face and speech apparatus. Aphasia is a language disturbance characterized by errors of grammar and word choice. Alexia is a reading inability that occurs either as a loss of reading ability in a previously literate person or as dyslexia, a developmental learning disorder. Finally, agraphia is an acquired disturbance in writing.

The first step in language assessment is to observe the patient's spontaneous speech in response to general questions during the intake interview. Behaviors observed include articulation problems, syntax errors, word-finding pauses, or any other marked change in speech production. Expressive language deficits are usually indicated by word retrieval difficulty or problems with word fluency. These are assessed using a picture naming test (e.g., Boston Naming Test) or a verbal fluency measure such as the D-KEFS Verbal Fluency (described under Executive Functioning Skills below). The Wechsler Individual Achievement Test—Second Edition (WIAT-II) Oral Expression subtest and the D-KEFS Proverbs subtest may also be useful in assessing a patient's expressive language abilities.

A second language area to assess is auditory comprehension or receptive language. Many language disorders cause impairment in this area. To measure auditory comprehension, a patient may be asked to respond to pointing commands (e.g., point to a chair) or yes-no questions, or given the WIAT-II Listening Comprehension subtest. The Token Test provides a more structured measure of receptive language. This test uses a series of tokens in various sizes, shapes, and colors arranged in front of the patient, who is asked to respond to a series of commands of increasing length (e.g., "Put the green circle on the red square").

Both oral word reading and reading comprehension are measured, using tests such as the Word Reading, Pseudoword Decoding, and Reading Comprehension subtests of the WIAT-II, the Reading Decoding subtest of the Wide Range Achievement Test 4 (WRAT4), or the Nelson-Denny Reading Test. These reading skills are supported by different neuropsychological functions and must be assessed separately. Inability to decode words is typically a phonological problem, while reading comprehension is influenced by several factors, such as attention and working memory. Spelling and written expression can be assessed by the

WRAT4 or WIAT-II Spelling subtests and the WIAT-II Written Expression subtest. Usually math skills are assessed with other academic skills, using the WRAT4 Math Computation, or WIAT-II Numerical Operations and Math Reasoning subtests.

### ***Executive Functioning Skills***

Executive functioning involves several complex cognitive skills mediated by the frontal lobes, including planning, sequencing, inhibition, flexibility, organization, reasoning, and problem solving. Working memory allows the individual to maintain internal representations in order to guide behavior, and as such, is an important part of self-control. Difficulties in executive function are associated with several conditions (e.g., attention deficit/hyperactivity disorder, or AD/HD).

Planning involves complex problem solving to achieve a goal. Planning is most often assessed with a tower test, such as the Tower of London or the D-KEFS Tower Test. These tests require the rearrangement of colored balls or disks on pegs to match a model, using rules that define acceptable moves. Maze tracing tasks provide an alternative measure of planning.

Response inhibition is the ability to delay a response or to not respond to nontarget stimuli. Many neuropsychological tests use a measure of rule violations to assess response inhibition. For example, on a tower test, rule violations occur when the patient uses two hands to solve the item, after being told that this is not an acceptable move. Errors on a Stroop color-word interference trial also indicate difficulties with response inhibition, when patients are unable to refrain reading the word when they are only to name the ink color. Finally, most continuous performance tests include a measure of the number of times an individual responds to nontarget stimuli, indicating a problem with response inhibition.

Working memory is viewed as an executive function skill that allows an individual to hold information in mind while performing an operation on it. It is measured using the WAIS-III Digit Span (Digits Backward), Arithmetic, and Letter-Number Sequencing subtests. Another useful test for measuring working memory is Auditory Consonant Trigrams (ACT), which requires the patient to hold three consonants in mind while counting out loud backward from a given number by threes for intervals varying from 0 to 36 seconds.

Concept formation and reasoning tasks can be thought of as measures of abstract thinking, problem

solving, and organization. Several subtests on the WAIS–III measure this component of executive functioning, including Comprehension, Similarities, and Matrix Reasoning. Other measures of concept formation and reasoning include the Wisconsin Card Sorting Test and the D-KEFS Sorting and Twenty Questions subtests.

Finally, verbal fluency can be considered both an executive function skill and a language component. Verbal fluency involves auditory attention, working memory, word production, mental processing speed, and vocabulary storage. It is typically measured with a test such as the Controlled Oral Word Association test (COWA) or the D-KEFS Verbal Fluency test. There are two parts to these tasks. The first measures letter (phonemic) fluency. The patient is instructed to generate words beginning with a given letter (e.g., F, A, S) in a limited time period. Letter fluency relies on working memory to facilitate word retrieval and keep track of recent responses. In category (semantic) fluency, the patient is asked to name as many items in a category (e.g., animals) as possible in a limited time period. Typically category fluency is easier for patients to perform than letter fluency, since information is stored in categories within long-term memory.

### ***Learning and Memory***

A common initial complaint of neuropsychological dysfunction is memory problems. Learning and memory are assessed using a variety of methods, depending on the type of memory being measured. The WAIS–III Digit Span (Digits Forward) subtest is one measure of immediate recall (encoding), while Digits Backward is a measure of working memory. The WAIS–III Information subtest is sometimes considered as an indicator of long-term memory, but is dependent on the individual's academic history.

New learning typically is assessed using a list learning exercise, such as the California Verbal Learning Test, 2nd Edition (CVLT-II) or the Rey Auditory Verbal Learning Test (RAVLT). In the CVLT-II, the examiner reads aloud a list that contains 16 common words, each of which belongs to one of four categories (fruits or spices). The patient is then asked to recall as many of these items as possible. The examiner records how many items the patient is able to recall over several repeated trials, and whether or not category information is being used. Next, an interference list is administered. Immediately after the recall of the interference list, the patient is asked to

recall the trial list again. Finally, after a longer delay of about 20 minutes, the examiner asks the client to recall the trial list a final time. The RAVLT follows a similar pattern, although there are no categories on the lists that are administered, which may make it a slightly more difficult test.

The CVLT-II and the RAVLT are particularly useful because they contain a recognition trial following the final recall trial. It is important to differentiate a patient's ability to voluntarily recall information from his or her ability to recognize it as something he or she previously heard. A difference between recall and recognition of list items allows the examiner to determine if the information was learned and stored, learned and forgotten, or never learned.

Story recall (e.g., WMS–III Logical Memory) is another method of assessing verbal learning and memory that allows the individual to use context clues to aid recall. Visual memory can be assessed using the WMS–III Faces subtest or other tests included in the visual-perceptual exam.

### ***Visual Perception, Constructional Ability, and Sensory-Motor Abilities***

A neuropsychological assessment should include an evaluation of visual perception and constructional abilities, both right hemisphere functions, and sensory and motor abilities. Visual perception consists of two independent process, visuo-perceptual ability and visuo-spatial ability. Visuo-perceptual deficits can take several forms, including visual agnosia (deficits in object and facial recognition) and form or pattern discrimination problems. Object recognition is commonly measured using an object naming test (e.g., the Boston Naming Test). Pattern discrimination is measured using the WAIS–III Matrix Reasoning and Symbol Search subtests. Facial discrimination can be measured by WMS–III Faces test.

Visuospatial deficits include visual neglect, problems with visuospatial judgment (position and orientation of objects), and topographic disorientation (difficulties on navigational tasks). Visual neglect can be measured using cancellation tests (e.g., D-KEFS Visual Scanning) or drawing tests, such as asking the patient to draw a clock, house, or flower. Visuospatial judgment can be assessed with a drawing test, or with the use of a line orientation test (e.g., Benton Judgment of Line Orientation). Finally, the patient's behavior is observed for any difficulties with navigation (e.g., getting lost in familiar surroundings).

Constructional ability is the capacity to draw or assemble an object from memory or by copying a model. Deficits in this domain cause patients to have difficulties integrating parts into a whole. These deficits are typically measured with a copying task (e.g., Rey Complex Figure Test) or a block assembly task (e.g., WAIS–III Block Design subtest).

Sensory and motor abilities are assessed because results can provide information about lateralized cortical problems. Sensory tasks measure the ability to perceive tactile input, and are measured by finger discrimination tasks. Motor speed and control are measured by finger-tapping tasks. Motor programming (e.g., planning, implementing, and automating new motor routines) is measured by imitating hand positions. Fine motor skills include visual motor precision and dexterity, and are measured by finger-tapping or maze-tracing tasks. Finally, motor strength is measured using a hand dynamometer.

### **Mood and Personality**

As a final domain, mood and personality are assessed to determine any evidence of thought, anxiety, or other mood disorder. The presence of psychiatric symptoms can affect scores on neuropsychological measures. Tests used to screen for symptoms include the Beck Depression Inventory, the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), and various behavioral rating scales.

### **Interpretation and Report Writing**

The final step in the evaluation involves the interpretation of the results and preparation of a report. The report is used to inform the referral source and others about the patient, and to provide guidelines that may be used in treatment and remediation. It is good practice to avoid using technical or ambiguous terms, to be objective, to include relevant history but not inappropriate details, and to support all conclusions. All tests and procedures used are described, and performance on all tests is reported, not just scores that suggest some form of impairment. Finally, specific recommendations for the patient that are realistic and based on resources and services that are available are included.

### **Future Directions**

Neuropsychology is likely to continue growing as a psychological subspecialty, particularly as advances in

neuroscience continue to occur. Although most states do not offer specific licensure in neuropsychology, this may change in the future. Currently the only credential available to demonstrate competence is board certification or diplomate status achieved through peer review and examination. Several professional organizations have developed specific guidelines for training in neuropsychology. Minimum criteria for a clinical neuropsychologist now include a doctoral degree in psychology from an accredited university, an internship in a clinically relevant area, state licensure, and two years of specialty training in neuropsychology.

## NORMATIVE ISSUES

---

Normative issues are those based on intrapersonal and interpersonal concerns that could be expected to occur in the course of a life. When people think about issues that might compel someone to seek professional help, they often envision severe and potentially even life-threatening issues such as major depression, extreme anxiety, addiction, mania, debilitating phobias, and suicidality. These issues obviously deserve the attention of mental health professionals, and it could even be said that “social permission” is implicitly—and sometimes even explicitly—granted to attend counseling based solely on the severity of the difficulties experienced. Clients who are experiencing severe difficulties rarely question their “right” to be in counseling. However, numerous others could benefit from an objective counseling experience as they endeavor to cope with the struggles of everyday living. Some normative issues are developmentally based and could become more problematic for different people at different points in their lives.

This entry provides a brief overview of intrapersonal and interpersonal normative issues that could occur for individuals, couples, and families. While some individuals do seek counseling for severe and diagnosable mental illnesses, many more individuals experience aspects of these normative issues that are emotionally distressing and reduce satisfaction with daily life. These normative issues can also be resolved through counseling.

### Intrapersonal Issues

Many of the normative issues that occur in counseling are intrapersonal issues. *Intrapersonal* may be defined

as occurring or originating within one’s self. The following section outlines some of the more common individual presenting problems in counseling. Although the focus of counseling may be on the identified client, it remains important to consider the systemic and developmental context of the client’s struggles.

### Academic Problems

Beginning school requires transition, and normative academic issues could be expected when children begin preschool or kindergarten. For some parents, the early school years may be the first time they realize that their child is not mastering specific skills at the same pace as other children. Parents may understandably feel reluctant or resistant if a kindergarten or first-grade teacher suggests that their child be tested for a “learning disorder.” There is often misunderstanding about the definitions of learning disabilities, and mental health professionals may be able to assist parents to obtain accurate assessments, diagnoses, and information about potential learning issues.

Academic concerns are not limited to diagnosable learning disorders. School difficulties may involve other systemic and contextual issues, and multiple psychosocial factors may interfere with children’s abilities to perform in a school setting. When a child enters school, the structure of attending school requires adjustment for families and children. Time management issues suddenly become more prominent as parents attempt to accommodate their work and family life to the school schedule. The structure of school also requires that school staff act as surrogate guardians, and parents may feel uneasy with the idea of other adults disciplining their child (or they may realize that their parenting philosophies differ widely from the teacher or school philosophies). At this stage of life, children are also challenged by a fear of separating from parents, and this may cause feelings of stress or “school phobia.” Counselors can assist with school-related issues by acting as advocates for parents and children in the school setting, by providing consultation for school staff, by facilitating parent–teacher communication, and by providing recommendations for interventions based on the needs of the child, family, and school.

Another transitory and potentially stressful turning point in academic life occurs when young adults enter college. Both academic and social issues produce stress for college students. In particular, incoming

freshmen face academic pressures related to grades, test scores and grade point average, difficulties with time management, and the need to use new learning and study strategies to master large amounts of complex material. Undergraduates must also cope with social issues related to adjusting to a new environment, leaving home, and forming new relationships with peers and faculty. Some researchers have suggested that low social support is associated with psychological stress and negative perceptions of the college experience. College counseling centers are ideally situated to assist in the adjustment to college by developing programming to facilitate social interactions among college students and by providing counseling services for those in need.

## Anger

Anger is a fundamental and basic emotion common to the human experience. Feeling angry is a natural and typical reaction to many life events, and it is sometimes healthy to express anger in constructive ways. Unexpressed anger is linked to increased susceptibility to illness, high blood pressure, and low pain tolerance as well as depression. Although it may be important to express anger in some situations, anger can be problematic if it is experienced as a chronic emotional state or if it is expressed in destructive, hurtful, or violent ways. Therefore, anger management is a prevalent reason for people to seek counseling. Anger management refers to a set of strategies or interventions clients can learn in therapy in order to identify, acknowledge, express, and contain their feelings of anger.

Difficulties with anger management may be an issue for multiple age groups. Young children may exhibit behaviors such as scratching, biting, throwing tantrums, or destroying toys. Parents may attend counseling to learn and practice parenting strategies to effectively decrease aggressive behaviors of children. During grade school and high school, bullying occurs. Bullying refers to intentional acts of aggression displayed by one student against another student. Overt acts may include name-calling, pushing, shoving, or hitting, whereas covert acts of bullying may include spreading gossip or ostracizing students from social interactions. Dawn Newman-Carlson and Arthur M. Horne suggested that counselors may be able to intervene with bullying by implementing schoolwide programs to increase teachers' abilities to manage acts of

anger in the classroom. Adults may also seek or be court ordered to counseling due to anger issues expressed in road rage situations, domestic violence, aggression in the workplace, or abuse of children. Adults may benefit from individual, group, or couples counseling to learn about ways to assertively express anger in healthy and constructive ways.

## Stress

Stress is the body's physiologic response to perceived threats. When individuals experience stress, heart and respiratory rates increase, blood pressure rises, and digestive processes are accelerated. This is termed the *fight-or-flight* phenomenon and refers to the way the body prepares to either confront or flee from perceived danger. Stress results from the perception of external threats and pressures, and some amount of stress is necessary for survival. However, stress may become a counseling issue when it occurs frequently or for prolonged amounts of time. Chronic stress may interfere with the ability to cope with daily events, it may cause somatic symptoms, and it results in feelings of irritability, worry, or sadness. Ongoing, repeated exposure to stress increases susceptibility to disease and it may increase risk for depression.

There are typical life events that may cause stress at various points in life. Both positive and negative events may invoke a stress response. Starting a new job, a death in the family, having a baby, moving, and financial difficulties are all examples of common events that may induce the experience of stress. Stress results from both the event and the meaning that individuals assign to the event. Individuals may experience similar life events, but appraise the events differently to result in unique stress experiences.

As individuals struggle to cope with stress, counseling may be a beneficial place to learn skills and strategies to increase relaxation. Multiple interventions may be effective, including breathing strategies, progressive muscle relaxation, cognitive exercises to decrease negative self-talk, and time management.

## Anxiety

In contrast to stress, anxiety is often characterized by a generalized feeling of excessive fear and worry. The anxious feelings are not necessarily associated with any particular life event, although stressors may trigger or exacerbate anxiety. People who experience

anxiety typically realize that their worries are in excess of what might be considered reasonable by others; however, they find it difficult to control their fearful thoughts. Anxiety may be chronic and pervasive in multiple aspects of life, and it can become debilitating because it impairs the ability to function at home, school, work, and/or in social settings. Anxiety may cause symptoms such as irritability, muscle tension, digestive problems, and/or sleep disturbance.

Mental health professionals often think of anxiety disorders as a group of diagnosable conditions with very specific criterion. Counselors use the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* to diagnose mental health disorders. In relation to anxiety, the *DSM-IV-TR* outlines conditions such as phobias, obsessive-compulsive disorder, generalized anxiety disorder, and stress disorders related to extreme trauma. Panic attacks are sometimes associated with anxiety and include somatic symptoms related to breathing, cardiovascular functioning, digestive difficulties, and feelings of dizziness. Panic attacks are sometimes mistaken for heart attacks, and this may cause clients to fear that they are dying.

Interventions for clients who experience anxiety disorders may include psychoeducation about the differences between stress and anxiety, work to reduce negative self-talk which may induce anxiety, breathing strategies, progressive muscle relaxation, or guided imagery, among others.

## Sleep

Sleep is a complex process guided by the body's hormonal and neurological responses to light and darkness. On typical nights, humans progress through multiple stages of sleep including a period of rapid eye movement (REM), which is when dreams commonly occur. For health reasons, sleep should progress successively through each of these stages, and a healthy sleeper will usually cycle through all of the stages 4 or 5 times per night. Difficulties arise when sleep is disrupted, shortened, or limited. The impact of sleep deprivation is cumulative across time and the consequences of sleep deficit are staggering. People who are consistently sleep deprived are at high risk for heart disease, cancer, and early death. Sleep deprivation is linked to slowed reaction time, impaired cognitive functioning, and difficulties with emotion regulation. Many work-related accidents and injuries are due to

fatigue, and car accidents are often linked to sleep-related issues. Therefore, sleep deprivation is a normative concern that is often a critical issue for clients.

Sleep dilemmas can occur across the life span for multiple reasons and are presenting issues in counseling sessions. Adolescents are often sleep deprived due to discrepancies between their circadian rhythms and the demands of school schedules. People between the ages of 13 and 25 often experience a delay in their sleep patterns in which they have difficulty falling asleep prior to 11 p.m. However, most high schools require that teenagers arrive at school early in the morning. This disparity often creates issues of sleep deprivation for high school students. In college, time management difficulties are a frequent difficulty for first- and second-year students, and thus "pulling an all-nighter" is a common undergraduate experience. In adulthood, new parents often have difficulties adjusting to newborn sleep schedules because infants typically are unable to sleep through the night until approximately 6 months of age. Working adults may suffer from sleep deprivation due to challenges involved in balancing work and home life, requirements to do shift or night work, or jet lag from business travel. As adults age, their sleep patterns begin to change, and this may cause difficulties or concerns for older adults.

Counselors might provide assistance for sleep-deprived clients by providing psychoeducation about the importance of sleep and information about sleep hygiene. Counseling sessions may be used to develop strategies to combat insomnia, and mental health professionals can assess for more severe sleep disorders such as sleep apnea, narcolepsy, or sleepwalking.

## Interpersonal Issues

All of the above intrapersonal issues could be reason enough to seek out counseling, yet these issues may be exacerbated in the context of a relationship with another person. Furthermore, there are also issues that arise from simply being in a relationship with another person, whether or not there are intrapersonal issues in the mix. The following section will cover some of the more common interpersonal issues that bring individuals, couples, or families to counseling.

## Communication

Understanding, both being understood and understanding the other, is one of the keystones to any good

relationship. Clarity in communication and positive communication brings people closer and provides a space for intimacy, shared goal development, and relationship satisfaction. Thus, difficulties in communication may result in more than misunderstanding; they can cause severe breaches in trust and intimacy within relationships.

One common model for communication is the active listening model, which is based on the active listening that is done by a counselor when he or she is working with clients. This model of communication originated in the therapeutic work of Carl R. Rogers, a proponent of demonstrating unconditional positive regard, acceptance, and empathy for clients. By demonstrating active listening through reflective statements, “I-statements” that indicate a nonblaming stance, paraphrasing both the content and feeling behind what was said, and exhibiting a nondefensive posture both verbally and nonverbally, all individuals can improve their communication skills. Active listening is often taught to individuals in the workplace and to couples as they attempt to work through conflicts. When couples employ nondefensive and nonattacking active listening techniques in their communication, they are more likely to be able to work through their difficulties without anger or causing further damage to their relationship.

The active listening model has been criticized for not translating from the therapeutic relationship to a romantic or work relationship as easily as had been hoped. The difficulty is that the active listening model primarily emerged out of “one-way” therapeutic relationships where the job of the counselor was to be nonjudgmental and nondefensive. The critics of the active listening model reflect that in most two-way relationships it is very difficult to maintain a completely nondefensive stance. Thus, although active listening skills may be present, people may not use them in the midst of conflict. Still, teaching the basics of active listening can help with moderately conflictual communication and communication skills training is often part of non-crisis-oriented counseling.

### ***Relationship Distress/Divorce***

Being in close relation to another person romantically can be one of the most fulfilling and wonderful events in a person’s life. Yet, having a partner also involves negotiating the challenges of sharing one’s life and knowing someone else intimately. Coming from different families with unique ways of approaching

conflict, household chores, money management, parenting, emotionality, and displays of affection can produce different expectations for individual behavior in the couple and a sense of a “right” way of being in a relationship. Furthermore, relationships can also be challenged by developmental transitions and unplanned situations. For example, negotiating dual career issues, the transition to becoming parents or the discovery of infertility, parenting adolescents, coping with the “empty nest” when children leave the home, infidelity, sexual issues, and medical illnesses are all issues that could lead an individual or a couple to counseling. These challenges can cause great distress, as they affect not only the couple but also the family, work, and friendships.

John M. Gottman used outcomes from his extensive research into couple relationships to delineate indicators of problematic relational styles. Specifically, he proposed that it is not the simple occurrence of negative interactions that cause distress, but rather the *type* of interaction. He outlined four problematic ways of interacting that he termed the Four Horsemen of the Apocalypse: criticism, defensiveness, contempt, and stonewalling. Additionally, he discussed the concepts of positive sentiment override and its opposite, negative sentiment override. Positive sentiment override means that if the predominant feeling within a relationship is positive, then small slights or relational errors are overlooked or categorized as unimportant. Conversely, negative sentiment override occurs when the predominant emotion in the relationship is negative, then even an outpouring of positive expression is unlikely to affect the overall well-being of the couple. His studies have revealed that functional relationships exhibit a 5 to 1 ratio of positive to negative interactions within the relationship. When this ratio becomes unbalanced, conflict becomes the main way of communicating and neither partner is satisfied.

The ultimate result of continuing conflict in a relationship is the dissolution of the relationship in either a break-up or divorce. Different people approach grieving the loss of a relationship differently. For some, especially those who did not initiate the separation, the loss of a primary relationship is a devastating event. Others, who are able to make the dissolution of a relationship fit with their views of themselves, do not find the separation as traumatic. One factor that can influence how one reacts to the loss of a relationship is when in the life cycle that the break-up occurs.

For example, a college-age or early marital break-up, while painful, may be considered less devastating than a divorce when there are young children present or after a lengthy partnership.

## Sexuality

Difficulties with sexuality can present themselves at almost any point in the life cycle. When couples are first forming their relationship, negotiating sexual intimacy and the presence or absence of past sexually intimate relationships can be problematic. Once the relationship is formed and the couple decides to have children, research has shown that sexual satisfaction plummets with the birth of children and does not improve for several years. Once the children reach adolescence, the sexual concerns of the family turn from the parent couple to the adolescent children and their developing sexuality. Parents are often concerned with protecting children from falling prey to external influences rather than making good personal choices about sexuality. Once the children leave home, the midlife parent couple faces the challenges of getting to know themselves and their sexuality again. Finally, in later life, issues such as menopause, medical issues, general physicality, and the pervasive influence of negative stereotypes regarding elder sexuality can have an extreme impact on sexuality.

Many couples experience difficulty or discomfort as they attempt to discuss their own sexual concerns or as they attempt to discuss sexuality with their children. Therefore, it is not surprising that it is often difficult for clients to openly discuss their sexual concerns with a counselor. Difficulties with sexuality can happen at any point in the sexual response cycle (i.e., excitement, plateau, climax, and resolution), and these difficulties can change based both on internal factors such as stress, low self-esteem, depression, or anxiety, and on external factors such as relationship difficulties, career issues, or balancing the multitude of daily demands and the tasks of everyday living. Additionally, many couples and individuals feel that only medically diagnosable sexual problems—for example, vaginismus (painful contraction of the vagina), erection difficulties, dyspareunia

(painful intercourse)—deserve the attention of a counselor and do not realize that counseling can help with sexual enrichment. Yet, counseling can be very helpful for teaching couples to talk openly about their wants, desires, and difficulties, and for educating parents and children in the delicate sexual discourse that is necessary as adolescents began to discover their own developing sexuality.

## OPTIMISM AND PESSIMISM

---

Optimism refers to a hopeful disposition or a general belief that good things will happen, whereas pessimism describes a general expectation that bad things will happen. These constructs have been conceptualized as dispositional traits, as well as cognitive styles, and have been examined in relation to various outcomes. Generally, research indicates that optimism tends to be associated with a host of positive outcomes (e.g., higher levels of achievement and both mental and physical well-being), whereas pessimism tends to be associated with less favorable outcomes. However, under certain circumstances, optimism may be maladaptive. Counselors draw from various techniques when using these concepts in their clinical work, but cultural factors influence their use of interventions related to optimism and pessimism.

### Optimism and Pessimism as Dispositional Traits

Michael F. Scheier and Charles S. Carver view optimism and pessimism as personality traits and have derived a self-regulatory model based on expectancy-value theory to describe how these traits relate to human experiences. The expectancy-value approach assumes that behavior is goal directed. The term *expectancy* refers to the probability a person attaches to the likelihood of attaining a given goal, and *value* refers to the value the person places on a particular goal.

According to the self-regulatory model, goals give meaning to people's lives, but goals are subject to

change, based on various forms of feedback. Individuals who experience adversity while pursuing a particular goal reassess the situation and the likelihood of success. This reassessment could lead to the identification of additional resources or alternative approaches to attaining the goal, or to abandoning the goal entirely. Optimists, who are more likely than pessimists to expect that they will be successful in achieving their goals, tend to persist in pursuit of their goals, despite adversity. For example, an optimistic college student might deal with a poor grade on the first exam in Introductory Biology by meeting with the instructor and revising his or her study techniques in order to better prepare for subsequent exams. In contrast, a pessimistic individual might deal with the same situation by "giving up," avoiding the situation (e.g., no longer attending class), and/or dropping out of college.

Abandoning a goal that is unattainable can be adaptive when doing so leads to adoption of a more suitable alternative. For instance, a college student who continues to struggle with biology courses in pursuit of the goal of becoming a physician, might, upon assessment of the situation, decide upon a more suitable career path.

Optimists tend to remain more confident in the face of adversity than pessimists, and are more persistent in pursuing their goals. Optimists are more likely than pessimists to take direct action when dealing with problems, tend to be more planful when dealing with adversity, and take a more focused approach in their efforts to cope with problems. Furthermore, optimists tend to accept the reality of adverse situations more readily than pessimists. Optimists appear to have a greater ability to make the best of a bad situation, and

they appear to be better able to grow or otherwise benefit from negative life experiences.

### Optimism and Pessimism as Cognitive Styles

The notion that cognitive styles bear a causal relationship to our affective experiences derives from Aaron Beck's cognitive theory of depression. According to Beck, depression results from cognitive distortions involving a tendency to highlight negative information while ignoring positive information. In contrast, people who are free from depression engage in a form of cognitive distortion in which they emphasize positive information while overlooking negative information.

According to attribution theory, individuals attempt to explain the events that occur in their lives by "attributing" the cause to one of three dimensions: internal-external, stable-temporary, and global-specific. The internal-external dimension refers to whether an event was due to a person's own actions or was the result of some external force. The stable-temporary dimension refers to whether the cause of a particular event is one that will remain stable across time or is more transient in nature. The global-specific dimension refers to whether the cause of an event is one that will affect many areas of a person's life or only one particular area.

A pessimistic explanatory style involves attributing negative events to internal, stable, and global factors (e.g., "I failed my Spanish exam because I'm stupid"). In contrast, an optimistic explanatory style involves external, temporary, and specific causal attributions for negative events (e.g., "I failed my Spanish exam because my teacher did a poor job of explaining the material, I was having a bad day when I took the test, and I'm not particularly good at learning new languages"). Research has demonstrated that a pessimistic explanatory style is related to depressive symptoms and poorer physical health (e.g., suppressed immune function).

Individuals with an optimistic explanatory style often use problem-focused coping strategies that involve active attempts to cope with a problem by engaging in direct problem solving (e.g., dealing with the stress associated with an upcoming exam by studying in advance). In many cases, such an approach is highly adaptive. However, the use of problem-focused coping strategies may result in wasted effort when the problem is not subject to change or the individual does not have adequate

resources to implement such change. An optimistic explanatory style works well during childhood, adolescence, and much of adulthood, but it may be maladaptive in later life when individuals often face circumstances that are less amenable to change (e.g., declining health and the death of loved ones). Emotion-focused coping, in which individuals attempt to regulate their emotions, may be more adaptive than wasting time and energy on problem-solving attempts in such circumstances. It may be most adaptive for individuals to tailor their explanatory style to the particular event with which they are faced.

### Defensive Pessimism and Strategic Optimism

An alternative view is that "strategic" optimism and "defensive" pessimism are strategies that can be used selectively to deal with specific situations rather than stable traits or styles. *Defensive pessimism* refers to a cognitive strategy of setting low expectations for some upcoming event, thereby preparing for and protecting oneself from potential failure. For instance, a job applicant who is anxious about an upcoming job interview might predict that he or she is going to be unable to respond to interview questions appropriately and come across as a "fool" during the interview, despite previous success in similar situations. Then, after considering all the things that could possibly go wrong, he or she plans carefully to prevent each feared event from occurring.

*Strategic optimism* refers to a strategy of setting high expectations that are consistent with self-perceptions and past experiences. This strategy avoids thoughts about possible negative outcomes associated with an upcoming task while preparing for the task. For instance, a person who has to deliver a formal speech would demonstrate strategic optimism by anticipating on the basis of past performance that he or she will do well and beginning to prepare for the speech at an appropriate time.

### Development of Optimism and Pessimism

Although few studies have examined the genetic basis of optimism and pessimism, scholars generally provide heritability estimates of approximately .25 for these traits. Heritability estimates for other personality traits such as extraversion and neuroticism are

typically higher. Some psychologists believe this implies that heredity exerts an indirect influence on optimism and pessimism. For example, optimism may be influenced by the genes for extraversion and pessimism by the genes for neuroticism. An alternative explanation is that genetic factors directly influence the likelihood of success or failure. These experiences, in turn, stimulate the development of an optimistic or pessimistic explanatory style.

Environmental experiences are indeed believed to influence the development of optimism and pessimism in several ways. Based on past experiences (i.e., success versus failure), children learn to expect future success or failure. Early experiences of helplessness, such as repeated exposure to violence or growing up in poverty, may also predispose children to become pessimistic. Parental modeling of expectations of success or failure and parental instruction in problem solving also are believed to influence the development of optimism and pessimism. In addition, children may internalize attributions for success and failure provided by their teachers and other important figures in their lives.

Results from longitudinal research studies demonstrate that even elementary-school-age children may display pessimistic explanatory styles. These children are more likely than their nonpessimistic peers to become depressed over time, particularly if they experience negative life events. Psychologists are working to develop interventions aimed at changing the pessimistic explanatory styles of at-risk children to prevent depression. These programs (which are based on Beck's cognitive therapy approach) begin by introducing children to the link between thoughts and feelings. Children then learn to dispute their negative thoughts about the causes of events, and are encouraged to search for evidence for and against their beliefs and evaluate situations in a more realistic manner. The results of such programs appear to be promising.

### **Integrating Optimism and Pessimism Into Counseling Practice**

Counseling psychologists use several approaches when helping clients modify their optimistic and pessimistic explanatory styles. Some view cognitive therapy as an effective form of treatment for depression precisely because it reduces pessimistic thinking. This approach focuses on decreasing negative thinking. Others use a variant of cognitive therapy in which interventions are aimed directly at decreasing the use

of optimism-suppressing strategies and increasing the use of positive thinking.

Psychologists have a choice of a variety of interventions aimed at decreasing pessimism and/or increasing optimism. For instance, psychologists might choose one or more of the following approaches:

- Help clients identify and modify their belief that optimistic thinking—such as “If I allow myself to feel confident, I will not prepare enough for the exam”—can be dangerous.
- Use *positive visualization*, which involves having clients visualize challenges they are likely to face in pursuit of a particular goal. Clients are instructed to imagine coping successfully with each challenge as it arises, and to imagine eventually achieving a successful outcome.
- Use *invulnerability training* to teach clients to imagine feeling good about how they handled a particular situation even when things did not turn out the way they had hoped.
- Use the *silver lining* technique to encourage clients to identify at least one positive element associated with each negative experience they encounter.
- Use *pump priming* to help clients spontaneously engage in optimistic thinking more frequently. For instance, a client who is instructed to spend 30 minutes each morning reading an article that discusses altruism might be more likely to recognize prosocial behaviors in others throughout the day. This, in turn, can lead to a more optimistic outlook throughout the day.
- Have clients use an *antipessimism sheet* to record their responses to upcoming events (e.g., the “best,” the “worst,” and the “most likely” outcomes they can foresee). Later, the client and therapist discuss these responses, their relation to the actual outcome, and the impact of the optimistic, pessimistic, and realistic predictions on the outcome.
- Have clients commit acts of kindness (e.g., donating blood, visiting an elderly relative) and practice grateful thinking (e.g., making note of friendships for which the client is thankful). When done in an intentional, focused manner, these actions may lead to increases in subjective well-being.

A few cautions should be observed in considering the preceding information. First, much of what is known about optimism and pessimism as they relate to well-being has been derived from work with Caucasian Americans. Research suggests that the

influence of optimism and pessimism on mental health may be different for Asian Americans. There is some evidence that Asian Americans benefit more from interventions aimed at enhancing optimism, whereas Caucasian Americans benefit more from those aimed at reducing pessimism. Additionally, some authors have suggested that, rather than attempting to change either optimistic or pessimistic thinking in isolation, a more balanced approach aimed at helping the client to develop more realistic cognitions may be most beneficial. Finally, there may be times when an optimistic outlook can be disadvantageous, such as when the circumstances with which individuals are faced are due to factors beyond their control. Nonetheless, there appear to be a number of both physical and mental health benefits associated with optimism.

## OUTCOMES OF COUNSELING AND PSYCHOTHERAPY

---

Counseling and psychotherapy outcomes are the benefits (or harms) that derive for clients (patients or mental healthcare consumers) as a result of their experiences or treatment in therapy or counseling. Although it is generally assumed that therapy is an effective treatment for mental health concerns, this is not always the case. The determination of therapy outcomes involves a variety of issues and considerations.

### How Are Outcomes Evaluated?

Efficacy and effectiveness are two ways in which the outcomes of counseling and psychotherapy are discussed. *Efficacy* refers to the therapeutic benefits found in comparison of the treatment and a no-treatment control group within the context of a controlled clinical study. In contrast, *effectiveness* refers to the benefits of therapy that occur within a mental health practice context. In the former instance, the question is whether a treatment or intervention is found to achieve a greater benefit for clients than no treatment. If so, the treatment is said to be “efficacious.” In the latter instance, the question is one of how effective counseling is for those clients who seek and receive treatment within the community.

It is alleged that clinical studies create an artificial context in which the therapy that takes place is not characteristic of how treatments are provided in an actual community context. Consequently, finding that a treatment is efficacious cannot be assumed to mean that it is effective (i.e., is beneficial to clients in practice settings). Although there is merit in this criticism, effectiveness findings are generally compromised by the absence of a control group within a practice setting against which to compare client therapeutic gains. As a result, it may not be possible to convincingly determine whether the benefits derived by clients receiving counseling in community

settings are due to the treatment or to some other extraneous factors.

## Significance of Therapy Outcomes

In the consideration of counseling and psychotherapy outcomes, it is important to ask, “When is an outcome significant?” The significance of therapy outcomes can be evaluated in several ways. Outcomes can be evaluated in terms of their statistical significance, and they can be evaluated in terms of the clinical significance or clinical relevance.

### *Statistical Significance*

There are two types of statistical significance that may be considered when evaluating therapy outcomes. The first has to do with differences between or among treatment groups. The second has to do with the changes experienced by individuals within those groups.

Between-group differences are examined by comparing the outcomes of two different approaches to therapy (e.g., a new approach to therapy vs. an established approach), or by comparing the outcome of a specific therapeutic approach with a placebo treatment or a nontreatment (wait list) group (i.e., a control group). Whatever the comparison, if the research is designed so as to rule out extraneous factors as competing explanations for the change, statistical procedures may be used to determine whether the observed differences that appear between groups can reasonably be attributed to differences in the administered treatments or whether it is more reasonable to conclude that the differences are due to chance (e.g., sampling differences). If the difference between the outcomes of the treatment group and the comparison group is in the expected direction and unlikely to be due to chance sampling differences, then it can be concluded that the difference is statistically significant. In other words, the treatment group was more efficacious and yielded a statistically better outcome than did the comparison group.

Although the treatment outcome of one group may differ significantly from that of another group, this does not necessarily mean that the change that occurred was itself significant. Indeed, it is conceivable that the treatment group did not change at all, but rather the comparison group became significantly worse, relative to the treatment group. In order to

evaluate the statistical significance of change within the treatment group (i.e., the statistical significance of its outcome), a different approach is needed. In this approach, a group’s pretreatment performance on some relevant outcome variable is evaluated against its posttreatment performance on the same variable. If the difference between the pre- and posttreatment assessments is in the expected direction and not attributable to chance differences in the measurement of the outcome variable (measurement error), then the change (or outcome) is said to be statistically significant.

### *Clinical Significance (Clinical Relevance)*

While the statistical significance of outcome research findings can provide empirical support for different treatment approaches, it is important to note that just because there are statistically significant differences between groups does not mean that the groups differ in clinically significant ways. That is to say, although the treatment outcome for one group may differ from that of another and be in the desired direction, such a finding may not be clinically meaningful. For example, a treatment for depression might produce therapeutic change in a group of clients that is significantly different statistically from that of a placebo treatment, but this does not necessarily mean that those who received the treatment are no longer depressed. It simply means that as a group, they changed more than those who received a placebo treatment did. Furthermore, a statistically significant within-group pre-post difference does not necessarily mean that the individuals who received the treatment are meaningfully improved. It simply means that their posttreatment scores are reliably different from their pretreatment scores.

Several approaches to the evaluation of clinically relevant change have been proposed. Evidence that treated clients are indistinguishable from a nondisturbed reference group is probably the most convincing evidence of clinically meaningful change. Neil S. Jacobson and Paula Truax extended this notion by proposing a standardized statistical method involving two criteria for assessing clinical significance. First, the treated client should be more likely identifiable as belonging within a distribution of healthy persons than a distribution of troubled individuals. Second, the client change must be reliable; that is, it must be large enough that the pre- to posttreatment change cannot be attributable to measurement error—a criterion for

which there is a *reliable change index* that can be statistically computed. Notwithstanding the above discussion, statistical significance, rather than clinical significance, is the manner in which outcome efficacy is generally reported.

### Perspectives on Therapy Outcomes

The determination of the clinical significance of a therapy outcome is invariably related to the perspective of the outcome evaluator. Early efforts at examining therapy outcomes generally relied exclusively on therapists' impressionistic ratings of client improvement. Over time, outcome evaluation moved from the reporting of therapists' clinical impressions to the use of standardized therapist rating scales to measure general improvement.

Although the use of such scales constitutes an important improvement to the evaluation of therapy outcomes, the possibility of therapist bias in the provision of ratings is problematic. As an additional source of information, client self-reports of improvement are frequently included in outcome evaluations. Often these consist of global measures of improvement framed as judgments of the benefit or value to therapy or client satisfaction on posttherapy questionnaires. Other client self-report efforts include structured personality measures or symptom rating scales—generally collected pre- and posttreatment. Client self-report measures provide a unique and important source of information and perspective regarding change resulting from therapy that can be especially useful to therapists in gauging their effectiveness in providing treatment. Concerns about objectivity that may result from the use of therapist- and client-rated measures has led to the use of persons not involved in therapy who, as raters, are blind to the treatment status of research participants or clients. It has also led to the use of physiological measures and unobtrusive measures such as student grades, judicial records, sales records, and the like.

Hans H. Strupp and Suzanne W. Hadley proposed a tripartite model of therapeutic outcomes that captured three important, yet distinct, perspectives from which the relevance of therapy outcomes could be evaluated: (a) the perspective of the client as consumer, (b) the perspective of the therapist or mental health professional, and (c) society. In discussing their model, they provided a variety of different therapy outcome evaluation scenarios. For example, it is possible for the client to report improvement, while

neither the therapist nor others support that conclusion. Alternatively, the therapist may believe the client has improved, but the client does not. Another possibility is that both the client and therapist may report improvement on the part of the client, but others in the community with whom the client interacts do not see the same improvement. In other words, agreement of these perspectives on the outcome of therapy cannot be assumed. These differences in perceptions of the outcome and therapeutic benefit raise important concerns in terms of the evaluation of therapy outcomes. Suffice it to say, when considering therapy outcomes, it is important to consider that there are multiple legitimate perspectives to consider and often the perspectives are not consistent.

Benjamin M. Ogles, Michael J. Lambert, and Kevin S. Masters incorporated the notion of different legitimate perspectives on therapy outcome into a multidimensional model for considering therapy outcomes. Expanding on earlier perspectives, these researchers include the perspectives of relevant others such as the client's spouse, friends, and work colleagues, plus those of trained observers and institutional referents (i.e., school, work or hospital records, public records of arrest, etc.). In addition to this *social* dimension of outcome measurement and evaluation, they also proposed several additional dimensional perspectives: (a) content, (b) social level, (c) technology, and (d) time orientation.

The *content* dimension refers to the psychological area or aspect of the person on which outcome is being measure and against which efficacy is evaluated. It includes client behavior, cognitions/thoughts, and emotions. The *social level* dimension refers to the degree to which the outcome construct being measured is intrapsychic or internal to the person or interpersonal and external to the person. Intrapsychic constructs include moods, self-concept, cognition or beliefs, and behavioral deficits. Interpersonal constructs include such things as social and work adjustment, delinquency, and group interaction.

The *technology* dimension refers to the variability in the types of instruments that are used for the collection of outcome/change data. This dimension captures the fact that different measures and instrumentation may yield differentially favorable or unfavorable outcome findings. These discrepancies in therapy outcome findings may arise depending on whether outcome is assessed globally or specifically, directly or indirectly. Differences in the sensitivity of the

measurement technology to change on the construct being assessed may also result in outcome discrepancies. The final dimension, *time orientation*, reflects the degree to which the outcome assessment attempts to measure stable/enduring, traitlike features of the person rather than features that are unstable and more dependent on the state or contemporary circumstance of the client.

This multidimensional model suggests that therapy outcomes are best understood and most reasonably evaluated over a number of different dimensions and from multiple perspectives. However, in this regard, it is important to note that conclusions about the effects or outcome of counseling and therapy depend on the particular measure that is used in assessing change in therapy and from what perspective(s) that change is evaluated. In outcome assessment, the measurement tools that are used often are connected with particular theoretical orientations or schools of therapy. Notwithstanding the differences among various orientations toward counseling and psychotherapy, clinicians and researchers recognize the need to assess the outcome of therapy on aspects broader than the dimensions or aspects immediately specific to a particular theory or approach to therapy.

### Is Therapy Better Than No Therapy?

The fundamental question in terms of therapy outcome is whether clients receiving therapy are, at the conclusion of their experience, better off than those who need therapy but do not receive it. In other words, “Does counseling/psychotherapy work?” This is a question about the absolute efficacy of therapy. As suggested earlier, it is generally assumed that therapy is an effective treatment for mental health concerns; however, it is an assumption that has been and continues to be open to the scrutiny of researchers.

A notable first attempt to examine the evidence relating to the effects of therapy was conducted in 1952 by Hans J. Eysenck. As previously mentioned, the evaluation of the efficacy of therapy requires that the effects of treatment be compared with a no-treatment control group. To conduct his evaluation, Eysenck compared the outcomes found in 24 studies of psychodynamic and eclectic psychotherapy with spontaneous remission rates (i.e., rate of improvement in client functioning without benefit of therapeutic intervention) using two control groups. The results of Eysenck’s study were disconcerting, finding that

clients who received psychodynamic or eclectic therapy improved less than those in his control/comparison no-treatment condition. Not only did it appear that therapy was ineffective, it might also be harmful.

Eysenck’s study was not without critiques, as there were serious design problems with his research method. Responding to the challenge to therapy implied by Eysenck’s study, numerous reviews of aggregated efficacy studies of counseling and psychotherapy were conducted during the 1960s and 1970s. While having their own methodological problems, these subsequent studies generally yielded findings supportive of therapy’s efficacy.

Over the years, examinations of the efficacy of counseling and psychotherapy have reached different and even contradictory conclusions. It is noteworthy that these earlier reviews of the outcome literature often lacked objectivity and replicability. They generally involved narrative descriptions of each study included in the review, an evaluation of the results in terms of the type of evidence offered with respect to therapy outcome, and then an implicit summary of the findings to render an overall conclusion about therapy’s effectiveness. However, with the hundreds of outcome studies now available for consideration in evaluating therapy’s effectiveness (outcome), turning the thousands of pieces of evidence that derive from all of these studies into an integrated summary of the benefits of counseling and psychotherapy is problematic.

Although a single outcome study will reveal information about the benefits received by the participants of that study, the answer to the broad question of “Is counseling/psychotherapy effective?” requires the examination of the body of research that has addressed this question. More recent inquiries into therapy efficacy have used the statistical method of meta-analysis to examine the aggregated results of hundreds of different studies that have compared a group receiving counseling or psychotherapy with a control group. Briefly, meta-analysis consists of a set of statistical procedures that allow researchers to gain a comprehensive picture of the research on a question and an unbiased answer to the research question. Through meta-analysis, outcome data from many individual counseling and psychotherapy outcome studies are systematically aggregated, allowing the findings to be analyzed to achieve an answer to the larger question of whether therapy is effective. Unlike the research methods used in individual studies for which the client-participants serve as data points for analysis,

meta-analysis uses the summary statistics from individual studies as the data points for analysis. Although not without detractors, meta-analytic procedures provide a methodology to assemble an overall picture of therapy's effectiveness (relative to no therapy or a placebo treatment) and for comparing across studies of different approaches to therapy in order to investigate the relative efficacy of different treatments.

The first meta-analysis of the outcome of psychotherapy was conducted by Mary Lee Smith and Gene V. Glass. They analyzed the results of 375 published and unpublished therapy outcome studies. The results of their study produced an effect size of .68, which suggests that an average client receiving therapy would be better off (i.e., improved) than 75% of untreated (control group) clients. Although their results suggest that a proportion (34%) of untreated clients also improved (i.e., spontaneous remission), the success rate for those receiving treatment was 66%, leading them to conclude that the research showed the beneficial effects of counseling.

As with the challenges to Eysenck's methodology and findings, there have been critics of and challenges to Smith and Glass's meta-analytic findings. Subsequent meta-analyses of the therapy outcome literature have challenged the validity of those criticisms, while at the same time providing rather convincing support for the absolute efficacy of counseling and psychotherapy. Although it cannot be said that therapy is effective for everyone who seeks it, the likelihood of improvement is high for those in therapy, and much higher than for those left untreated.

### **Negative Outcomes in Therapy**

Research does support a conclusion that there are negative outcomes in therapy; that is, some clients do get worse. This research suggests that a relatively consistent 5% to 10% of clients deteriorate while participating in therapy. However, this does not mean that all instances of worsening that occur during counseling/therapy are the result of the treatment. Some clients may be on a progressive decline that a therapist is unable to stop. There are a number of factors related to the client, therapist, and treatment that are associated with negative outcomes during counseling/psychotherapy. Negative outcomes are more likely in clients being treated for borderline personality disorders and obsessive-compulsive disorders, as well as in clients with interpersonal difficulties and more severe problems at the start of therapy. Therapist

characteristics that are associated with negative outcomes include lack of empathy, underestimation of the severity of clients' problems, and negative countertransference. Experiential therapies are more likely to produce negative outcomes, as are minimal interventions for severely distressed clients.

### **Are Some Therapies Better Than Others?**

One of the interesting, but perplexing, aspects of counseling and psychotherapy is the great diversity of different schools and orientations that exist in the field. In the mid-1960s, one list documented over 60 different approaches to therapy. In 1975, a report of the Research Task Force of the National Institute of Mental Health (NIMH) noted over 130 different types of psychotherapy. Five years later, the number had grown to over 200 different forms of therapy, and in 1986, over 400 different therapeutic techniques were listed. Whether the list of therapeutic approaches has grown or shrunk since that time probably depends on who is doing the counting.

In light of the proliferation of approaches to therapy, it is reasonable to ask whether some approaches are better than others. Such a question is one of the relative efficacy of different treatments. Specifically, does Treatment X produce a better outcome than Treatment Y? In contrast to the evaluation of the absolute efficacy of a treatment ("Is Treatment X better than no treatment?"), researchers evaluate the relative efficacy of different approaches to counseling by contrasting one treatment against another.

In 1936, upon considering the claims of success (and eventually of superiority) of the proponents of the various then-current approaches to therapy, Saul Rosenzweig conjectured that despite purported differences in these various approaches to counseling and psychotherapy, they were essentially equivalent in terms of their outcomes. Borrowing a phrase drawn from Lewis Carroll's 1865 book *Alice in Wonderland*, Rosenzweig remarked, "Everybody has won and all must have prizes"—a phrase now referred to as the Dodo Bird conjecture, after the character in the book that proclaimed the winners of the oddly run Caucus Race.

Although a history of comparative outcome reviews will reveal mixed results in regard to the outcome superiority of various counseling and psychotherapy approaches, contemporary meta-analytic reviews of the comparative outcome research reach a

conclusion remarkably similar to that reached in the Dodo Bird conjecture. In general, and in terms of proportions of clients who improve by the end of therapy, differences between various forms of therapy are generally insignificant, but consistent with the absolute efficacy outcome finding noted above—that is, across different approaches to counseling and psychotherapy, there appears to be uniform efficacy.

### **Are Some Therapies Better Than Others for Certain Problems or Disorders?**

While the results of treatment comparison studies suggest little in the way of outcome differences between different approaches to counseling and psychotherapy, it is reasonable to speculate that outcome differences might exist for different therapies, depending on the problems or disorders toward which they were applied. Such a supposition is reflected in the question of what treatment works best for what specific problem. The implication in this question is that the comparison of various treatment outcomes is too gross a comparison to capture meaningful differences among therapy approaches for specific types of presenting concerns. Instead, it may be that one approach is best for treating depression, while another is best for treating anxiety, and so on. In this regard, detractors of the finding of uniform treatment efficacy (the Dodo bird conjecture) contend that the lack of findings of the superiority of certain various treatments is the result of researchers failing to take into consideration the effect of different treatments on different client problems or concerns.

That there is a vast array of different approaches to therapy has already been noted. Similarly, there are many different sorts of concerns, problems, and disorders that clients present to counselors and therapists. A cross-tabulation of treatments by disorders would be enormous. Adding therapist, client, and circumstantial variables to this mix would result in an impossibly large number of combinations for researchers to test and compare and for counselors and therapists to master.

Notwithstanding the enormity of the challenge posed by considering disorder-specific therapy, there is an increasing large body of research that supports the efficacy of particular treatments for particular problems. These studies provided the evidentiary basis for what are referred to as *empirically supported*

*treatments*. The results of meta-analyses comparing different treatments approaches for different problems, however, generally do not support an interpretation that certain treatments are more effective than others for specific client problem areas.

### **What Makes Therapy Effective?**

The question of what makes therapy effective is not an “outcome question.” Rather it a question about what goes on during therapy—the “process of therapy”—that leads to a therapeutic outcome. Considerable research has been and continues to be conducted that addresses this issue. It is beyond the scope of this entry to review that literature. Suffice it to say that different approaches to counseling and psychotherapy postulate factors specific to each approach as the mechanisms of therapeutic change. However, the findings that different approaches to therapy tend to be equally effective, and that there is little evidence to support the contention that different treatments are differentially effective for different client problems, do not support the argument that factors specific to particular counseling approaches account for change. These findings have led to research on aspects of the therapy process that are common to different approaches to counseling and therapy that might account for the consistency in therapy’s beneficial effects across these different approaches. These two perspectives on the therapy process—change as a function of orientation-specific factors and change as a function of common factors—are central to contemporary process research.

## OVERDIAGNOSIS

---

*See* UNDERDIAGNOSIS/OVERDIAGNOSIS

---

## PANIC DISORDERS

---

A panic attack is the sudden onset of intense apprehension, fearfulness, or terror, often associated with feelings of impending doom. In addition, symptoms such as shortness of breath, palpitations, chest pain or discomfort, choking or smothering sensations, and fear of “going crazy” or losing control are present. Panic disorder involves the presence of recurrent and unexpected panic attacks, followed by at least a month of persistent concern about another panic attack, or worry about the possible effects of having another panic attack.

The combination of unexpected attacks and persistent anxiety about recurrent episodes of physiological dysregulation, termed *fear of fear* or *anxiety sensitivity*, distinguishes panic disorder from other anxiety disorders in which panic episodes occasionally occur. Anxiety sensitivity is defined as fear of anxiety symptoms, which arises out of the belief that those symptoms are harmful. For instance, individuals with high anxiety sensitivity may believe chest pains signify an impending heart attack, whereas individuals with low anxiety sensitivity will regard such pains as merely unpleasant. To meet the criteria for panic disorder, the symptoms cannot be due to the direct physiological effects of a substance, a medical condition, or another mental disorder.

There are three types of panic attacks. An *unexpected panic attack* is a sudden, surprising, spontaneous, quick increase of panic symptoms and sensations that seem to arise without an obvious situational trigger or external stimuli. A *situationally bound attack* is one in

which a sudden surge of fear of terror is triggered by exposure to a situational trigger. Situational triggers can either be external, (i.e., a phobic object or situation) or internal (i.e., physiological arousal or sensations). These attacks are characteristics of specific phobias and occur whenever the situational trigger is present.

The third type of panic attack, a *situationally pre-disposed attack*, differs from a situationally bound attack in that exposure to a situational trigger increases the likelihood of panic but does not invariably precipitate it. Concerns about having another attack, or the impact of such, are often linked to the avoidance of specific situations or places. When the avoidance behavior meets the criteria for agoraphobia (i.e., avoidance of open spaces), panic disorder with agoraphobia is diagnosed.

### Panic Versus Anxiety

Although panic disorder is classified in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* as a type of anxiety disorder, the preponderance of research suggests that panic is qualitatively distinct from anxiety; that is, panic is not just a severe form of anxiety. Panic consists solely of fear, while anxiety comprises other dysphoric states in addition to fear. Sudden onset of symptoms also distinguishes panic from anxiety. Episodes of severe anxiety with gradual onset generally do not involve fears of dying or going crazy, and they do not involve as many symptoms as episodes of severe anxiety with a rapid onset. Panic arouses a flight-or-fight response to a perceived immediate

threat, whereas anxiety functions as vigilance for anticipating and coping with future threats. The cognitive content of panic involves imminent danger, whereas the cognitive content of anxiety is composed of worry about a variety of concerns.

### **Anxiety Sensitivity Index**

The Anxiety Sensitivity Index (ASI) has received considerable support as a valid self-report measure of the fear of anxiety symptoms. It consists of 16 5-point Likert scale items that express concerns or worries about the possible consequences of anxiety. It has a high degree of internal consistency and satisfactory test-retest reliability over 3 years. It has a single factor structure, with a low level of shared variance with general trait anxiety. Clients experiencing panic score about two standard deviations above the normative mean on the ASI and significantly higher than clients diagnosed with generalized anxiety disorder (GAD).

### **How Panic Arises**

Research on the causes of panic is still in its early stages, but in general the evidence suggests that panic can occur for a variety of reasons. Cognitive theory hypothesizes that catastrophic misinterpretation of certain bodily sensations (e.g., interpreting palpitations as signs of impending heart attack, dizziness as imminent collapse, or derealization as going crazy) causes panic attacks. Catastrophic misinterpretations escalate anxiety and intensify bodily sensations until they culminate in panic.

Support for this theory is available from retrospective studies in which patients who experienced panic reported that thoughts of imminent threat or danger tended to precede their attacks. Catastrophic thoughts occurred after the detection of a specific bodily sensation but before the emergence of panic. If the cognitive hypothesis of panic is correct, interventions that reduce the likelihood of a catastrophic misinterpretation should reduce the likelihood of panic. This hypothesis has been validated by numerous research studies.

Catastrophic misinterpretation is not the only cause of panic attacks. Some patients recalled having catastrophic thoughts only after they experienced panic symptoms. In another study, 27% of those who experienced panic attacks reported that fearful thoughts did not precede the attacks.

## **Psychological Treatments for Panic Disorder With Agoraphobia**

Psychological treatments that do not include in vivo exposure to feared situations are ineffective in treating phobic fear. Patients told to avoid contact with phobic situations generally experience no improvement or even a worsening of their symptoms. Exposure to feared situations, delivered in a variety of ways, can be effective. For example, between-session exposure to feared situations, assigned by the therapist as self-exposure homework, typically increases treatment effectiveness. Scheduling frequent exposure sessions and spacing exposure sessions do not differentially affect dropout or relapse rates. Furthermore, minimizing or maximizing the patient's level of anxiety during exposure sessions does not seem to affect outcome.

Behavioral psychologists hypothesize that escape from anxiety-provoking situations reduces anxiety and strengthens agoraphobic avoidance behavior. However, the research evidence suggests that it is not "escape" per se that reduces anxiety. It appears that the sense of control experienced by those who believe they have the option of escaping the fear-inducing situation that fosters fear reduction.

The demonstrated effectiveness of exposure therapy has prompted research to investigate adjunctive techniques that might enhance outcome. Overall, relaxation and cognitive procedures add little to exposure in vivo unless they specifically target panic. Cognitive therapy for panic disorder with agoraphobia is helpful only when it incorporates exposure to feared situations in addition to altering persistent tendencies to catastrophically misinterpret bodily sensations. This requires eliciting the client's misinterpretations and assessing the evidence for and against their validity. For example, a cognitive therapist would inquire whether the last episode of chest pains turned out to precede a heart attack. Alternately, the client could engage in shallow breathing for a few minutes to induce bodily sensations similar to the last episode of panic attack, while taking care to ensure that the bodily sensations do not escalate into a panic attack.

Research shows that individuals with panic disorder with agoraphobia experience a significant decrease in panic, anxiety, and agoraphobia avoidance when treated with graduated exposure in vivo, graduated exposure plus relaxation training, and graduated exposure plus cognitive therapy. Both adjunct treatments increase the effectiveness of exposure in vivo;

the cognitive therapy adjunct seems to increase the effectiveness of exposure more than the relaxation training adjunct.

There is a preponderance of evidence supporting the effectiveness of cognitive-behavioral treatment for both agoraphobic avoidance and spontaneous panic. Another non-cognitive-behavioral approach, 3 sessions of psychoeducation and 12 sessions of nondirective psychotherapy, also has demonstrated some effectiveness in reducing panic. These findings should be replicated and the therapeutic factor identified to enhance understanding of what made that particular treatment modality a potential option for treating panic.

## PARADOXICAL INTERVENTIONS

---

Numerous definitions of *paradox* have been offered that contain several commonalities. First, they involve a statement that is contrary to received, or common, opinion. Second, they involve some sort of logical contradiction. For example, in ancient Crete, Epimenides the

Cretan said, “All Cretans are liars”—which leads to a logical contradiction because he cannot be believed, whether or not he is telling the truth. Third, they often involve an explicit communication that is embedded within an implicit framework that communicates a different message. The famous “I want you to be more spontaneous” injunction is an example, because the explicit message can only be obeyed if it is not obeyed. This is a *double bind*, which some consider the essence of paradoxical statements. The paradoxes inherent in such statements are not easily disentangled and often can be resolved only by leaving the relationship entirely. Fourth, paradox can be seen as an example of dialectical thinking in philosophy, in which any statement may contain its opposite. It can be seen from these definitions that the key word behind paradox is *contradiction*.

Within a help-seeking counseling relationship, paradoxical interventions can be seen as those in which the counselor seems to advocate the continuation or even the worsening of problems rather than their elimination. Some writers see this as *decontextualizing* the problem by altering the context and the supporting environment in which the symptoms appear. In the process, the symptoms are redefined as solutions.

### Paradox in Ordinary Life

Paradoxical ideas and ways of thinking are as old as humanity, especially in Eastern philosophy and major world religions. The *Tao Te Ching* (*Way of Virtue*), written by the founder of Taoism, Lao Tzu, contains much paradoxical advice, such as getting what one wants by being open to receiving its opposite. Buddhism likewise contains many paradoxical ideas. For example, if one seeks enlightenment, one will be unable to attain it because he or she will have attachment to enlightenment itself. Christianity contains many paradoxical statements such as, “Whoever would be great among you must be your servant.”

In lay terms, paradox is similar to reverse psychology, and many examples can be found in literature. *Reverse psychology* is a term that describes a situation in which advocacy of one course of action persuades someone to do the opposite. Examples include Tom Sawyer persuading his friends to paint his fence by describing it as a privilege rather than a task. Likewise, attempts to censor works of art or literature paradoxically result in those works becoming more attractive.

## Paradoxical Interventions in Counseling

Alfred Adler is widely thought to be the first therapist to make explicit use of paradoxical interventions. The use of these techniques stemmed from Adler's belief that a successful power play against the therapist results in increased patient self-esteem and therefore patient improvement. Thus, in a sort of "therapeutic judo," Adler encouraged patients to rebel against him. Adler often used humor in prescribing his injunctions.

From a behavioral point of view, in the 1920s, Knight Dunlap developed an approach that he called *negative practice*. This involved deliberately practicing behaviors that one wanted to eliminate rather than attempting to avoid them. Dunlap saw this as a way of bringing them under control. In doing so, he argued against the law of habit formation, which states that repetition of a response increases the probability of its recurrence.

Perhaps the best known therapist to use paradoxical interventions and the first to use that term explicitly was Viktor Frankl. As part of his logotherapy, he developed what he called *paradoxical intention*, in which he encouraged patients to do or wish for that which they most feared. For example, a patient who was very afraid of contamination was urged to wish to become as dirty as possible. This is very similar to what later was called *symptom prescription*.

### Types of Paradoxical Interventions

There are different ways of classifying paradoxical interventions, but one useful system makes a distinction between compliance-based and defiance-based interventions. All of the specific paradoxical techniques can be placed within one or the other.

#### **Compliance-Based Interventions**

These interventions are used with the expectation the client will comply with the counselor's suggestion or directive and thereby improve. In the original compliance-defiance model, clients who were low on psychological reactance, that is, the tendency to resist interpersonal influence, were expected to do best with these strategies. There are several types of compliance-based interventions.

##### **Reframing**

Also called *positive connotation*, this involves a shift in meaning of the problem behavior from

negative to positive. For example, feeling depressed might be reinterpreted as exquisite sensitivity to one's internal feelings and a willingness to make sacrifices for the good of others. Anxiety might be reframed as a strong sense of caring about the outcome of a task. A related technique is *relabeling*, in which the label of a problem behavior is changed without changing its meaning. Negative connotation can also occur, in which a positive behavior is relabeled as negative, but that rarely occurs because there is little point.

##### **Symptom Prescription**

This strategy involves urging the client to perform or even exaggerate the very behavior that is the problem in the first place. As a compliance-based intervention, it derives its power from the new control the client has over a behavior that was formerly seen as uncontrollable. A variant is *symptom scheduling*, in which the client is directed to (for example) feel deliberately anxious or fight with his or her spouse at a particular time. By implication, if the behavior can be controlled in one direction, it can be controlled in the other. This technique is very similar to Frankl's *paradoxical intention*.

#### **Defiance-Based Interventions**

These interventions are used with the expectation the client will defy the counselor's suggestion or directive and thereby improve. They are similar to Adler's original conceptualization. In the original compliance-defiance model, clients who scored high on psychological reactance were expected to do best with these strategies because they would resist the therapist in order to maintain their freedom.

##### **Symptom Prescription**

Although listed as a compliance-based intervention, this can also be conceptualized as a defiance-based intervention. With reactant clients, it derives its power from the fact that client resistance to the counselor's suggestion or directive to perform the problem behavior deliberately reduces the frequency of that behavior. By implication, the behavior is under more conscious control than the client originally thought. Reactant clients tend to resist *symptom scheduling* as well, often finding it more onerous than simply giving up the problem behavior.

### Restraining Strategies

In using this technique, the counselor either tells the client not to change the problem behavior (*prohibiting change*) or to change very slowly and carefully (*inhibiting change*). With this directive, reactant clients can resist the counselor only by changing, which is the point of therapy in the first place. It also empowers clients by placing the locus of change squarely upon them. The most common use of restraining strategies has been in sex therapy, where impotent couples are told not to attempt to engage in sexual activity for a period of time. With the pressure to perform thus removed, spontaneous sexual activity often occurs, much to their surprise.

### Positioning

Here the counselor deliberately exaggerates clients' negative views of themselves; useful when the counselor suspects these negative statements are designed to elicit positive comments from others in a "fishing for compliments" exercise. Adlerian therapists refer to this as "spitting in the client's soup." This technique should be used judiciously to avoid sounding sarcastic or uncaring. It should not be used with clients who have a truly negative view of themselves.

## Effectiveness of Paradoxical Interventions

The research evidence has shown that paradoxical interventions are effective, although not more so than alternative treatments. It does appear, however, that their effectiveness increases more over time than that of other treatments. Two possible reasons have been suggested for this "sleeper effect." First, paradoxical interventions, by their very nature, may require a period of incubation as clients reorganize their cognitive meaning system. Second, they may result in clients' attributing behavior change to themselves rather than to the counselor, thus leading to a sense of personal empowerment.

Some concerns have been raised about the acceptability of paradoxical interventions, or even if they are ethical. Although the evidence is sparse and somewhat mixed, it does suggest that counselors who use paradoxical interventions may be viewed less positively and seen as more manipulative. In addition, there is evidence that paradoxical interventions are seen as less acceptable. An explanation of the

rationale behind these interventions may help the client be more accepting of these interventions. Of course, that removes some of the mystery that some writers believe is an important part of the counseling and psychotherapy process.

*See* SELF-EFFICACY/PERCEIVED COMPETENCE

## PERSONALITY ASSESSMENT

Personality assessment, in its broadest sense, includes any technique that is used to describe or make inferences about the characteristic traits, attitudes, beliefs, values, needs, motives, emotional states, coping styles, or aspirations of an individual. Personality assessment can take many forms, including an Internet dating questionnaire, an epitaph, a letter of recommendation, a psychodiagnosis, an integrity test administered as part of an employment application, and a psychobiography based on a historical record.

For the present purposes, however, three major functions of personality assessment will be considered: assessment in the service of basic research and theory explication; assessment in applied psychology,

including therapeutic, organizational, and forensic settings; and assessment in self-exploration. These different functions of personality assessment determine the personality characteristics to be measured and the instrument or method to be used.

### What to Measure: The Content of Personality

Personality characteristics constitute a fuzzy set, populated by constructs as diverse as extraversion, physical attractiveness, creativity, sexual orientation, gender, and psychopathology. Yet there is some consensus, for at its core, personality is now generally conceptualized at three strata or levels of analysis. In parallel with these three levels of analysis, three goals of personality assessment can be described. The most ambitious of these is *understanding*, followed by *explanation*, then *description and prediction*.

#### **Narrative Accounts**

The deepest of the three strata is the life story, a set of meanings that unfolds over time and which can be linked into a narrative account. The outstanding characteristic of the life story is its individuality. Assessment at this level is aimed at an abstract *understanding* of the person, and typically occurs in specialized contexts such as case studies, biographies, and epitaphs. The narrative account can serve as an implicit criterion against which respondents evaluate the validity of more shallow and more quantitative assessments of personality.

#### **Characteristic Adaptations**

Characteristic adaptations represent a heterogeneous middle level of analysis. These include motives and related mechanisms such as coping and defensive styles, and cognitive factors such as schemas, plans, generalized expectancies, and beliefs. Characteristic adaptations also include developmental constructs such as stage of personality development. A prominent measure at this level is the Washington University Sentence Completion Test, a measure of ego development. Given the heterogeneity of this level, assessment of characteristic adaptations serves many functions. For heuristic purposes, however, the primary reason for assessing characteristic adaptations is to achieve an *explanation* of why behavior does or does not occur.

#### **Traits**

The most accessible and easily quantified level of personality is that of the trait or disposition. The primary objective when assessing personality traits or dispositions is the *description and prediction* of behavior.

#### **The Meaning of Traits**

Traits, the primary unit of personality description, are relatively enduring ways in which individuals differ. Assessment at the level of traits is variable centered and nomothetic, focusing on differences among individuals, as opposed to the person-centered and idiographic approach that focuses on individuals, and that typically characterizes assessment at deeper and more abstract levels of personality.

Because people differ in many ways, psychologists must decide which differences are worthy of study. While evolutionary, psychoanalytic, and behavioral perspectives have been influential in suggesting traits that are worthy of attention when assessing personality, a more pragmatic, data-driven approach has generally held sway. At the most basic level, trait attributions are made based upon simple summaries of past behavior, and because what has happened in the past is likely to recur, traits can serve as valid predictors of future behaviors. Beyond this summary approach, if one takes into account characteristics of the situation as well, traits can help explain behavior and contribute to an understanding of the person. For example, an observation that “Jane has panic attacks in crowds” might lead to an inference of the form that “Jane will not go to the party because she is agoraphobic.” Trait attributions can and frequently do go beyond the trivial and tautological.

#### **The Five-Factor Model**

Factor analytic results indicate that many of the 18,000 words used to describe personality in the English language represent variations of five basic traits. The five-factor model (FFM) and its variants provide the most important contemporary perspective on traits, effectively serving as a paradigm for contemporary research in personality assessment. The five factors, sometimes referred to as the Big Five, are generally conceived of as extraversion, neuroticism, conscientiousness, agreeableness, and openness to experience.

*Extraversion.* The breadth of the five factors can leave them open to multiple interpretations, and this is particularly true for extraversion. For Jung, extraversion and introversion describe an individual's preferred direction of attention or focus: Extraverts focus on the external, shared world, while introverts focus on internal, idiosyncratic experiences. Eysenck offered a physiological explanation of extraversion (which he labels *extroversion*) based on the level of arousal of the reticular activating system. Eysenck viewed extraverts as endogenously understimulated (and so desirous of external stimulation and excitement), and introverts as overstimulated and consequently likely to seek quieter settings. An affective conception is that extraverts are more likely than introverts to experience and report positive affect. From a behavioral perspective, the most visible component of extraversion is social motivation and social skill. The combination of social interest and positive affect has given rise to the interpretation of extraversion as *surgency* or lively sociability.

Given the breadth of the extraversion-introversion dimension of personality, it is difficult to imagine conditions under which the dimension would not be relevant in understanding individual differences in the motivations, behaviors, and satisfactions experienced by individuals. Extraversion is measured in most comprehensive personality inventories used by psychologists.

*Neuroticism.* Neuroticism represents a tendency to experience negative affect, anxiety, and emotional upset; its opposite may be understood as well-being, emotional stability, or adjustment. Neuroticism is associated with sensitivity to punishment rather than reward, and with behavioral inhibition rather than activation. The Americans with Disabilities Act may proscribe the explicit measurement of neuroticism in applied settings (i.e., selection) because psychological health is conceptualized as a component of physical health.

*Conscientiousness.* Conscientiousness is a broad factor that includes discipline, a respectful attitude towards rules, work ethic, behavioral constraint, organization, responsibility, socialization, and impulse control. Conscientiousness is the Big Five trait most closely linked with job performance, and it is associated with scores on the integrity tests that are widely used in personnel selection. The relationship between conscientiousness and social conformity has led to some confusion, for the term *conscientiousness* also

denotes a stage in personality development characterized by the transcendence of mindless conformity and the internalization of a moral code.

*Agreeableness.* Agreeableness includes attributes such as likability, friendly compliance, warmth, and conformity, as well as communion, the positive core of the feminine gender role. Agreeableness is the most evaluative laden of the five factors. Because agreeableness is related to likability, observer ratings of agreeableness are more subjective and may show less interrater consensus than observer ratings of other traits.

*Openness.* The core of Openness to Experience includes breadth of interests, curiosity, and cultural sophistication. For some authors, this factor includes characteristics as diverse as flexibility, intelligence, political liberalism, and hypnotic susceptibility. There is both less cross-cultural generalizability and less agreement on the specific content for this factor. Openness generally appears as the smallest of the factors in statistical analyses. Nonetheless, both the core of openness and its more peripheral, less consensual components are empirically important in many settings.

### Beyond the Five Factors

The five-factor model is one useful starting point for personality assessment, but additional personality characteristics have been identified that may be conceptualized as lying between, beyond, and beneath the five factors. The five factors may be thought of as geometric axes between which other sets of axes may constitute a richer or more theoretically sound framework. For example, Extraversion and Neuroticism may be rotated to the arguably more elemental concepts of Anxiety and Impulsivity. Similarly, beyond the five factors, additional traits appear to be poorly represented in the five factor space, including spirituality, attractiveness, insight, ambition, unpleasantness, manipulativeness, egotism, seductiveness, integrity, thriftiness, risk taking, and humor. Beneath the five factors lie narrower constructs that may have more predictive utility. Punctuality, in some circumstances, may be more informative than the broader trait of Conscientiousness by which it is imperfectly subsumed.

The five-factor model derives ultimately from lay usage; the factor analytic methods that underpin the model provide, in principle, a nonredundant and potentially comprehensive set of tools for describing

the universe of personality trait terms. However, lay usage is not the only useful source from which to derive personality characteristics, and statistical elegance is not the only meaningful criterion governing the selection of a variables. For these reasons, many psychologists continue to prefer other sets of constructs, including those based on the theoretical positions outlined by Jung, Murray, Eysenck, and Gough. These positions are considered in the next section.

### **How to Measure: The Tools of Assessment**

The most widely used methods of assessing personality include self-report measures and observer rating scales. Self-report measures, in turn, include multitrait personality inventories, single-trait personality scales, and projective techniques.

#### ***Personality Inventories***

Personality inventories are questionnaires that provide scores on a number of traits or characteristics. These measures typically take 30 to 75 minutes to complete and are intended for administration to adults. Most inventories consist primarily of statements (e.g., “I would be uncomfortable in a foreign city”) or adjectives (e.g., “friendly”). Respondents are instructed to answer using a dichotomous format (e.g., true/false) or a 3-to-7-point (e.g., *agree strongly, agree, neither agree nor disagree, disagree, or disagree strongly*) format.

#### **The NEO Personality Inventory, Revised**

The NEO Personality Inventory, Revised (NEO PI-R) is the best-known and most empirically supported measure of the five factors. The NEO PI-R can be administered in a third-person form for generating observer ratings as well as the more familiar first-person form. In addition to measures of the five factors, the NEO PI-R also provides measures of 30 lower-level facet scales, such as Gregariousness (a facet of Extraversion), Trust (Agreeableness), and Aesthetics (Openness). A short form of the instrument, the NEO Five-Factor Inventory (NEO-FFI), provides scores only at the level of the five broad domains. In addition, a second abbreviated test, the NEO-4, is available for applications in which the measurement of Neuroticism is inappropriate. The NEO PI-R is an expansion of two earlier tests, the NEO (which did not

include measures of Agreeableness or Conscientiousness), and the NEO PI (which included facet scales for only the first three domains).

The NEO PI-R has been translated into some 25 languages, and it has been used extensively in studies ranging from descriptions of American presidents to cross-sectional studies of personality development. With respect to the latter, the five factors generally appear quite stable throughout adulthood. In vocational assessment, several studies indicate that the NEO PI-R complements, but does not replace, measures of vocational interest. Scores on the NEO PI-R Neuroticism scale have been shown to decrease during therapy, while Conscientiousness scores have increased during the course of a drug rehabilitation program. NEO PI-R domain scores also appear to be related to the psychologist’s assessments of treatment appropriateness and efficacy. Clients who score high on Openness are rated as benefiting from client-centered techniques, while those who score high on Neuroticism have been found to benefit from journaling and vocational techniques.

Unlike many other personality inventories, the NEO PI-R does not include indices of faking or invalidity beyond a few questions at the end of the test that directly ask if the respondent has answered honestly, accurately, and in the correct order. The rationale behind excluding validity scales includes empirical evidence that when protocols that are identified as “invalid” are excluded, test validity may be reduced rather than increased, suggesting that “invalid” protocols do, in fact, contain information. Individuals differ in the probability that they will respond in a less than honest fashion, and these individual differences may be meaningful.

#### **Other Measures of the Five Factors**

The five factors can be measured in a number of ways in addition to the NEO PI-R. Explicit measures of the five factors include the Hogan Personality Inventory (HPI), which is widely used in organizational settings, and two measures based on simple adjectives, the Goldberg Big Five Markers and the Interpersonal Adjective Scales-Revised. Additional measures of some or all of the characteristics are available that are not directly derived from the five-factor model. For example, Conscientiousness can be measured by the Rule-consciousness and Perfectionism scales of the Sixteen Personality Factor Questionnaire (16 PF),

the Organization and Responsibility scales of the Jackson Personality Inventory (JPI), the Control and Harm-avoidance scales of the Multidimensional Personality Questionnaire (MPQ), and scales including Responsibility and Achievement via Conformance on the California Psychological Inventory (CPI). However, the different measures of the five factors should not be considered interchangeable. For example, the externalizing dimension of the CPI—a form of Extraversion—is largely a measure of social skills rather than social interest. High scores on Agreeableness on the NEO appear to reflect more obsequiousness and less charm than high agreeableness scores on the HPI.

### **The Sixteen Personality Factor Questionnaire**

As with the measures of the five-factor model, the Sixteen Personality Factor Questionnaire (16 PF) was derived from factor analyses of traits selected from analyses of words appearing in the English language that describe personality. This measure, originally developed by Raymond B. Cattell in 1949 and presently in its fifth edition, now labels its measures using familiar terms (e.g., Warmth and Social Boldness) rather than the neologisms (e.g., Schizothymia and Threctia) that were used in earlier editions. The measure incorporates a multilevel approach to assessment; scores are provided on both medium-bandwidth primary dimensions and the five global factors of Extraversion, Anxiety, Tough Mindedness, Independence, and Self-Control. The 16 PF continues to include items that measure reasoning skills or intelligence as well as core characteristics of personality. This confounding of distinct constructs such as cognitive ability and personality in the scores obtained from the 16 PF is regarded as an undesirable feature by some psychologists.

### **The Eysenck Inventories and Related Measures**

A number of measures are based on models of personality that derive from a concern for both psychometric and biological parsimony. The most prominent of these is the family of measures derived by Hans Eysenck. The Eysenck Personality Questionnaire Revised (EPQR) is a 100-item instrument that measures the three broad factors of Extraversion, Neuroticism, and Psychoticism. The label for the last of these is at best

idiosyncratic, as high scorers on the measure are much more likely to be impulsive than to suffer from serious psychopathology. In addition to the three main factors, the EPQR includes a Lie scale that measures conformity, the desire to create a favorable impression, and the potentially invalidating tendency to “fake good.” A 48-item short form, the EPQRS, is also available.

The Zuckerman-Kuhlman Personality Questionnaire (ZKPQ) is similar in length to the EPQ-R, and measures five alternative factors: Impulsive Sensation Seeking, Neuroticism-Anxiety, Aggression-Hostility, Activity, and Sociability. It also includes a validity scale titled Infrequency. Impulsive Sensation Seeking has been found to be associated with a variety of risk-taking behaviors.

Cloninger's Temperament and Character Inventory (TCI) includes 240 items measuring four biologically based parameters (i.e., Novelty Seeking, Harm Avoidance, Reward Dependence, and Persistence) and three dimensions of character (i.e., Self-Directedness, Cooperativeness, and Self-Transcendence). The TCI is used primarily in psychiatry and medicine.

### **The California Psychological Inventory**

The California Psychological Inventory (CPI) is presently available in a 434-item version and an abbreviated 260-item form. Twenty-nine scales are included on both of these forms; all but two of the corresponding scales correlate .89 or higher.

The core constructs measured by the CPI are “folk concepts” whose relevance is demonstrated by their use in a variety of societies or cultures. Measures of these scales, alone and also in combination, are designed to predict how others will see the respondent and how the respondent will behave in consequential situations. Folk concept scales include measures of interpersonal orientation or social tendencies (such as Dominance and Sociability) and orientation toward rules and norms (such as Responsibility and Self-Control). These themes are also assessed in two broader “vector” scales, which conjointly form a fourfold typology. Alphas are extraverted, Betas are introverted, and both resonate to rules. Gammas and Deltas, extraverts and introverts, respectively, are skeptical of rules and resistant of the status quo. A third vector assesses degree of realization (i.e., the extent to which the potential embodied in a type is met).

Taken together, the vector scales form a structural model based on the premise that each of the four types

may contribute constructively to society, or struggle uniquely. Alphas may be benevolent leaders at high levels of realization, but at lower levels of realization they may appear tyrannical and authoritarian. Betas may appear to be saintly at higher levels of realization or constricted conformists at lower levels. At higher and lower levels, respectively, Gammas may be voices for progressive change or histrionic whiners, and Deltas may be visionary or suffer internal conflicts that lead to psychosis.

The typology is empirically useful in predicting meaningful life events. For example, among high school students, the typology is related to the likelihood of attending college. The rate of college matriculation is greatest for Alphas and lowest for Deltas. Similarly, there is a disproportionate representation of Alphas and Gammas among students enrolled in graduate programs in counseling psychology. While these findings are informative, the limitations of typologies discussed below in the section on measures based on Jung's model must be kept in mind.

In addition to the two central themes and the typology, the CPI also includes folk scales that assess academic and cognitive functioning (e.g., Achievement via Conformance and Achievement via Independence) and personal style (e.g., Flexibility and Psychological Mindedness or Insightfulness). The CPI also provides a number of scales that assess constructs such as Law Enforcement Orientation (LEO), Work Orientation, Managerial Potential, Leadership, and Creative Temperament. Many of these scales were empirically developed, using criterion groups or correlations with behavioral criteria.

The length of the CPI, even of the shorter version, may appear to be daunting, but the potential for tedium is moderated by the true/false response format and the use of engaging item content. For example, the Communitary scale, which exists in part to assess random or improbable responding, includes items that are intended to be ego-syntonic (e.g., "I would fight if someone tried to take my rights away" and "Education is more important than most people think"). The CPI is useful as a clinical tool for revealing the strengths of a client, as well as for predicting performance in a range of settings, from health care to corrections, and from academic to organizational.

### Measures Based on Murray's Model

Probably the most fertile theoretical basis for personality tests is Henry Murray's theory of needs.

Douglas N. Jackson's Personality Research Form (PRF Form E), the most prominent self-report needs assessment inventory, includes 352 items that assess 20 needs (e.g., Achievement, Affiliation, and Play). A substantial body of research attests to its validity for a variety of functions, including personnel selection and the assessment of leadership style. A second measure of needs, now largely of historical interest, is the Edwards Personal Preference Schedule (EPPS). The EPPS was unusual in its attempt to control for socially desirable or acquiescent test-taking styles by relying on a forced-choice response format. Ultimately, the elimination of variance attributable to response style reduced the validity of the instrument and it has fallen into relative disuse. Finally, the Adjective Check List consists of 300 adjectives that the respondent checks or leaves blank. Responses are scored to yield measures of 15 needs (e.g., Dominance, Exhibition, and Aggression).

### Measures Based on Jung's Model

Based on Carl Jung's theory of psychological types, the Myers-Briggs Type Indicator (MBTI) is among the most widely administered measures of personality. All three forms of the MBTI currently in use (the 126-item Form G, the 93-item Form M, and the 144-item Form Q) provide measures of Extraversion-Introversion (E-I), Sensing-Intuition (S-N), Thinking-Feeling (T-F), and Judging-Perceiving (J-P). These four dimensions are each treated dichotomously in interpreting the MBTI, and are combined to yield 16 types. This accounts in large part for the popularity of the measure. For example, describing a person as an ENFP—an Extraverted, iNtuitive, Feeling, Perceiving type—provides a potentially parsimonious and cognitively economical description, and also offers the person an identity-buttressing membership into an imagined community of like-minded people.

Typologies are compelling, and it is likely that the changes that have been seen in other tests, notably the structural model grafted on to the CPI, have occurred in part because of the success and popularity of the MBTI. Unfortunately, there are costs associated with the reduction of scores to simple dichotomies. In particular, the reduction of important dimensions of personality to dichotomies oversimplifies the rich diversity of personality that exists among individuals. Furthermore, most individuals will score near the mean on at least one of the four dimensions of the test. As a consequence, the type classification of most individuals is likely to change if the individuals are tested

at another time. These shortcomings seriously reduce the value—but not necessarily the popularity—of this approach to assessment.

The newest form in the MBTI family, form Q, provides measures of narrow facets (subscales) as well as a typological classification based on the four broad dichotomies. For Extraversion-Introversion, the core facet is Initiating-Receiving; for Judging-Perceiving, the core facet is Systematic-Casual.

While research indicates that the narrow facets provide additional information over and above what is provided by the broader measures, there is, as yet, little evidence regarding their specific content. The heart of the MBTI remains its typology, the popularity of which has led to a number of competing, and superficially similar, measures of Jungian type. These include the Grey-Wheelwright Jungian Type Survey, the Singer-Loomis Type Development Inventory, the Keirsey Temperament Sorter, and the Personal Preferences Self-Description Questionnaire.

#### **Measures Intended for the Measurement of Psychopathology**

The 338-item revised Minnesota Multiphasic Personality Inventory (MMPI-RF), scheduled for publication in late 2007, includes a set of Restructured Clinical (RC) scales that have been developed rationally on the basis of psychometric structure. The RC scales are shorter than the original clinical scales. More important, they are intended to separate the ubiquitous factor of generalized anxiety or “demoralization” from other, narrower concerns assessed in the instrument such as somaticization (i.e., a form of mental illness in which an individual manifests a psychiatric condition in the form of a physical complaint). This offers the potential for the RC scales to be less redundant and more informative than the original scales.

Another important feature of the MMPI-RF is its multilevel approach to the assessment of dysfunction. At the broadest level, three measures are included: Emotional/Internalizing (assessing emotional and mood disorders), Thought (assessing irrational cognitive processes), and Behavioral/Externalizing (assessing problems associated with under socialization or acting out). Beneath this, Somatic scales and Interest scales assess narrower problems such as Head Pain Complaints and Aesthetic-Literary interests, respectively. In addition, the MMPI-RF includes measures of dimensions of personality disorder, including Aggressiveness and Introversion. Empirical research is

needed to determine whether the Restructured Clinical scales offer an improvement over the prior measure.

#### **Single-Trait Personality Scales**

In addition to the comprehensive inventories considered above, personality assessment via self-report frequently is based on responses to personality scales that assess single traits. Examples include the Beck Depression Inventory, the Locus of Control scale (and related narrower measures, such as the Health Locus of Control scale), and instruments that assess psychache (i.e., unbearable psychological pain associated with suicidality), alexithymia (i.e., the inability to describe emotions), adult attachment, body image, attitudes toward eating, and various social, cultural, and political attitudes.

#### **Projective Measures: Sentence Completion Tests**

Projective techniques may be seen as a combination of behavioral assessment (what a person does), self-report (what a person says), and the judgment of an observer. This entry mentions only sentence completion forms, a type of projective test that appears particularly important in personality assessment. Sentence completion forms are semistructured measures in which respondents are asked to complete stems such as “My mother . . .” The best validated of these is Loevinger’s Washington University Sentence Completion Test, a measure of social and cognitive maturity that has been widely used in studies of personality development, particularly in the college years. A second sentence completion measure is the Rotter Incomplete Sentences Blank, which assesses emotional adjustment.

#### **Measures for Observer Ratings**

Psychologists often systematize their view of a client to clarify impressions of the client, to allow comparison between the client and real or prototypical others, and to assess progress during therapy. Numerous instruments are available for quantifying observer impressions of personality, including several of the measures considered above (e.g., the NEO PI-R). A number of rating scales are also used for this purpose. For example, the Structured Interview for the Five-Factor Model of personality (SIFFM) is a 120-item semistructured interview that provides measures of maladaptive and adaptive aspects of the five

factors. The SIFFM is particularly targeted at the measurement of personality disorders and related pathology.

The Q-sort is one noteworthy approach to the use of rating scales. A Q-sort consists of a set of ratings in which comparisons are made *ipsatively*, or between characteristics (e.g., Fred is more aggressive than he is ambitious). This contrasts with the more typical practice of making *normative* comparisons, which are comparisons between people (e.g., Fred is more aggressive than Erik).

Several personality measures use the Q-sort methodology. The California Q-set includes 100 items derived from clinical use. Raters are asked to assign items to 7 to 9 categories. Items assess numerous aspects of personality and defensive style (e.g., “Appears to have a high degree of intellectual capacity,” “Is uncomfortable with uncertainty and complexity,” and “Anxiety and stress find outlet in bodily symptoms”). Versions for describing both adults and children are available. A longer Q-set, the Shedler-Westen Assessment Procedure (SWAP-200), has been advanced as well. Q-sets are time consuming to complete because they require a series of paired comparisons between items in order to place ratings into a prescribed distribution. The impressive empirical results that have been found with Q-sets suggest that this time may be well spent.

### Current and Future Directions

Personality assessment is in a period of creative ferment, characterized by the creation of new measures and the revisions of existing ones, driven by advances in technology, and abetted by a culture that views testing, assessment, and accountability largely as instruments for the common good. Yet the contemporary success of personality assessment brings with it risks. For example, the explosion of the Internet has brought online personality measures of unknown validity into millions of homes. In some cases, these unscreened, unvalidated, and widely used measures may bring insight to those seeking self-exploration, but in many cases this will not be true. Unfortunately, public skepticism about the validity of personality tests, once attributable to the claims of astrologers, palmists, and phrenologists, is today encouraged by the widespread availability of amateurish personality inventories.

In formal assessment, no one instrument will be ideal for every application. The function of testing, the interests of the client and counselor, and the contexts of culture and community should guide the

selection, and, where needed, the development of measures. People are different, and the tools of personality assessment, properly used, will continue to assist counselors in understanding, capturing, and furthering human individuality.

## PERSONALITY DISORDERS

---

Personality disorders (PDs) pose a major challenge to the modern profession of mental health care. Unlike depression, anxiety, and other disorders that are more commonly the focus of treatment, personality disorders are generally understood to be pervasive, inflexible, maladaptive, and enduring expressions of personality. People with PDs exact a heavy cost from themselves and society, as well as place considerable pressure on the mental health care system. The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* is currently the most widely used diagnostic system to diagnose personality disorders, particularly in the United States. The International Classification of Diseases (ICD-10), maintained by the World Health Organization, is another important diagnostic system.

The *DSM-IV-TR* distinguishes among 10 PDs that are conceptually organized into three clusters, designated Cluster A (odd-eccentric), Cluster B (dramatic-erratic), and Cluster C (anxious-fearful). Cluster A includes paranoid, schizoid, and schizotypal PDs. Cluster B includes antisocial, borderline, histrionic, and narcissistic PDs. Cluster C includes avoidant, dependent, and obsessive-compulsive PDs. In addition, the *DSM* allows for the diagnosis of personality disorder not otherwise specified (PD-NOS), which can be given when a person meets general criteria for a personality disorder and traits of several PDs, but does not meet the criteria for any one specific disorder. This entry reviews what is known about the personality disorders in the *DSM-IV-TR*. The review will focus on the features, etiology, prevalence, comorbidity, course, and treatment of the various PDs.

### Features of *DSM-IV-TR* Personality Disorders

#### *Cluster A (Odd-Eccentric)*

##### **Paranoid Personality Disorder**

According to *DSM-IV-TR*, Paranoid PD (PPD) is characterized by a consistent pattern of distrust of the motives of other people. People with this disorder

assume that people will intentionally exploit, harm, or deceive them, and they often feel deeply injured by another person. They are frequently reluctant to become close to others out of fear that any personal information they reveal about themselves will later be used to hurt them. Individuals with this disorder can be severely sensitive to criticism and therefore are likely to feel attacked, threatened, or criticized by others. They might read hidden meanings or malevolent intentions into innocent remarks, mistakes, or compliments. It is also very difficult for a person with PPD to forgive others for perceived insults or injuries. Prolonged hostility, aggression, reactions of anger to perceived insults, and jealousy without adequate justification are also common.

##### **Schizoid Personality Disorder**

*DSM-IV-TR* notes that those with schizoid PD (SPD) are characteristically detached from and uninterested in social relationships. People with SPD may choose careers or hobbies that allow them to avoid contact with other people, and they typically are uninterested in developing intimate or sexual relationships. In addition, those with SPD have a flatness of affect that leads others to experience them as cold and aloof. Not only do they derive little pleasure from sensory or interpersonal experiences, they are also usually unmoved by the disapproval of others. They might claim that they do not experience strong emotions, whether positive or negative. Further, people with SPD may fail to respond to social cues, such as a smile, leading others to perceive them as self-absorbed, socially inept, or conceited.

##### **Schizotypal Personality Disorder**

According to *DSM-IV-TR*, schizotypal PD (STPD) is characterized by a pattern of marked interpersonal deficits, discomfort with close relationships, behavioral eccentricities, and distortions in perception and thinking. The *DSM* notes that individuals with STPD will often seek treatment for anxiety, depression, or other emotional problems. Although persons with this disorder may experience transient psychotic episodes, they must be distinguished from those with Axis I psychotic disorders that feature more persistent delusions and hallucinations. Ideas of reference are a common feature of STPD, as are odd beliefs such as magical thinking, extreme superstition, or a preoccupation with paranormal phenomena. In addition, people with STPD might have perceptual distortions such as bodily illusions or sensory alterations, and many

have odd thought and speech patterns. For example, their speech might be excessively vague, abstract, or loose, yet still maintain basic coherence. They often appear uncomfortable and act peculiar in social situations, and their affective expression is frequently constricted or inappropriate.

### **Cluster B (Dramatic-Eratic)**

#### **Antisocial Personality Disorder**

As defined by *DSM-IV-TR*, antisocial PD (ASPD) is a pervasive pattern of irresponsible behavior and disregard for the rights of others that begins by childhood or early adolescence. People with this disorder repeatedly engage in unlawful and/or reckless behavior. Frequently victimizing others and blaming their victims for their own fate, they typically lack remorse for having hurt or mistreated another person. Those with ASPD are prone to impulsiveness, irritability, and aggressiveness, which often leads to physical fights or assault, and they have a reckless disregard for the safety of themselves or others. In addition, they might repeatedly fail to honor work or financial obligations, or display other evidence of consistent and extreme irresponsibility. Manipulativeness, deceitfulness, and dishonesty are also central features of this disorder, often making collateral sources of information necessary for accurate diagnosis. In order to be diagnosed with ASPD, the *DSM* system requires that an individual be at least 18 years old and must have met at least some criteria for Conduct Disorder prior to age 15.

#### **Borderline Personality Disorder**

According to the *DSM-IV-TR*, individuals with borderline personality disorder (BPD) show a pattern of instability in various psychological and interpersonal domains. Their concept of self and feelings about self are markedly unstable, although thoughts about the self generally have a negative quality. Consonant with this characteristic, their beliefs, goals for the future, and social and sexual preferences may change often. These individuals' views of others also show extreme volatility; they frequently begin relationships by idealizing the other and assuming a closer relationship than normal. When the other pulls away or otherwise disappoints, the borderline individual can suddenly switch to demonizing him or her.

Individuals with BPD frequently show labile emotions, changing from relative calm to intense anger or dysphoria in response to very subtle cues from others, which tends to further exacerbate interpersonal problems. In addition, they frequently report chronic feelings of emptiness, diffuse anxiety, and irritability.

Behaviorally, those with BPD are frequently suicidal and prone to self-injury. While the rate of completed suicide is high in this population—around 10%—these behaviors frequently serve to regulate their chaotic emotions, communicate their feelings to others, and keep others from leaving them. Other behavioral symptoms of BPD include angry, hostile outbursts and impulsivity (e.g., reckless behavior, binge eating, or substance use), and transient psychotic symptoms.

#### **Histrionic Personality Disorder**

The *DSM-IV-TR* notes that the emotional expression of individuals with histrionic PD (HPD) is often excessive, theatrical, shallow, and rapidly shifting. Public displays of emotion or temper tantrums are common, yet they begin and end too quickly to be perceived as genuine in feeling. In addition, the speech of a person with HPD may be overly impressionistic in style, yet lacking in detail. For instance, strong opinions might be dramatically expressed without giving adequate reasons to support them.

#### **Narcissistic Personality Disorder**

According to *DSM-IV-TR*, the central features of narcissistic personality disorder (NPD) are pervasive grandiosity, a constant need for admiration, and a lack of empathy for others. An individual with NPD has a sense of self-importance and an attitude of arrogance that might manifest in boastfulness, pretentiousness, or disdain. An overestimation of one's own abilities and a devaluation of others are characteristic of this disorder. Also common is a preoccupation with fantasies about one's own brilliance, beauty, or expected success.

A person with NPD usually requires constant attention and admiration, and may become furious with others who do not shower them with compliments or accolades. They typically have fragile self-esteem, so their self-importance might alternate with feelings of unworthiness. They frequently either experience feelings of envy of other people, or imagine that others are envious of them. The sense of entitlement that is central to NPD often precludes the recognition of

others' abilities, needs, feelings, or concerns. Individuals with this disorder might discuss their own problems or concerns in lengthy detail, yet react with insensitivity or impatience to the problems of others. To others, these individuals appear cold, disinterested, disdainful, snobbish, or patronizing.

### **Cluster C (Anxious-Fearful)**

#### **Avoidant Personality Disorder**

According to *DSM-IV-TR*, persons with avoidant personality disorder (AVPD) are characterized by pervasive social inhibition and discomfort in social situations, feelings of inadequacy and low self-esteem, and hypersensitivity to criticism or rejection. Although they long for close relationships, they avoid activities that involve interpersonal contact and have difficulty joining group activities. Persons with this disorder assume that other people will be critical and disapproving. They act with restraint in social situations and have difficulty sharing intimate feelings for fear of criticism, disapproval, shame, or ridicule. They have a strong need for certainty and security that severely restricts their ability to become close to others, and they typically are not able to establish new friendships or intimate relationships without the assurance of uncritical acceptance.

People with AVPD frequently feel socially incompetent, personally unappealing, or inferior to others. Therefore, they are reluctant to engage in new activities and they tend to be shy, inhibited, and quiet to avoid attracting attention to themselves. In addition, they are hypervigilant about subtle cues that suggest criticism or rejection and typically feel extremely hurt when they detect such behavior.

#### **Dependent Personality Disorder**

According to the *DSM-IV-TR*, the central characteristic of dependent personality disorder (DPD) is a pervasive need to be taken care of that begins by early adulthood. People with this disorder have an exaggerated fear that they are incapable of doing things or taking care of themselves on their own, and therefore rely on other people (usually one person) to help them. They rely heavily on advice and reassurance from others in making decisions. Because of their lack of self-confidence, it is difficult for people with DPD to begin tasks on their own without being assured that

someone is supervising them. They may appear to others to be incompetent because they believe that they are inept and they present themselves as such.

*DSM-IV-TR* notes that because of their dependency on others, people with DPD often fail to learn basic independent living skills, and frequently find themselves in abusive or otherwise unbalanced relationships. It is not unusual for people with DPD to feel unrealistically fearful of being abandoned. They are typically passive and unwilling to disagree or become appropriately angry with the person on whom they depend. People with DPD usually feel highly uncomfortable being alone because of an exaggerated fear of helplessness or the inability to care for themselves. The end of an intimate relationship will often be followed by urgent efforts to replace the person with another source of closeness and support.

#### **Obsessive-Compulsive Personality Disorder**

The *DSM-IV-TR* describes obsessive-compulsive personality disorder (OCPD) as a pervasive pattern of perfectionism, orderliness, and inflexibility that begins by early adulthood. People with OCPD have an excessive need for control that interferes with their ability to maintain interpersonal relationships or employment. They are typically preoccupied with rules, lists, schedules, or other minor details, and their rigidity and stubbornness about these trivia often create difficulty for them in both work and personal relationships.

In addition, the *DSM* notes that individuals with OCPD often sacrifice personal relationships in favor of work, and become obsessively devoted to productivity. They hold both themselves and others to unrealistic standards of morality, ethics, or values. They are also reluctant to delegate tasks to others because they insist that everything be done their own way. The *DSM* further notes that individuals with OCPD might be reluctant to throw away worthless and unsentimental objects for fear that they might be needed at a later date. Furthermore, people with this disorder might hoard money and tightly control their spending, believing that money should be saved for a future catastrophe.

### **Etiology**

The empirical data on the etiology of PDs is extremely limited and complicated by the fact that PDs are a heterogeneous group of disorders. Most

theories of PDs acknowledge that they are at least partially genetically determined and that temperamental and behavioral abnormalities during childhood can precede their development. These predispositions are believed to interact with environmental experience to shape personality during the early years of development. Environmental factors are believed to range in severity and influence as a function of biological predispositions and protective factors. Trauma can often be considered a predisposing factor to the development of personality disorders; however, it is not necessary nor sufficient for the development of PDs.

The evidence for a genetic contribution to the development of personality pathology, while plausible and generally accepted, is mixed. A number of studies have focused on the heritability of personality traits that theoretically relate to PDs, such as neuroticism or extraversion. Few studies have examined the heritability of specific PD diagnoses. The heritability of specific PDs has been found to vary, with schizotypal PD most strongly linked to genetic influences, antisocial PD linked to both environmental and genetic factors, and borderline and narcissistic PDs typically showing the smallest estimates of heritability. Given the contradictory findings and limitations of the study designs, it is safe to say that the heritability of certain PDs like borderline and narcissistic, although reasonable to posit, is uncertain at this time, and there is clearer evidence for environmental contributions to the development of these disorders. Joel Paris suggested that the etiology of PDs is unlikely to be underpinned by simple, linear, narrow-causal processes; complex interactive processes among variables are likely to be involved in the etiology of PDs.

### Prevalence and Comorbidity

Prevalence estimates for *DSM-IV* personality disorders vary according to the definition of personality disorder and the type of sample used. For example, Myrna M. Weissman found that pre-*DSM-III* era epidemiologic studies of PDs yielded overall rates between 6% and 10% in the general population, but the *DSM-IV* estimated prevalence rates of 10% to 20%. Similarly, community studies typically have found lower estimates of PD prevalence than does research based on clinical samples. Community studies of the prevalence of *DSM-III* or *DSM-III-R* PDs (almost all of which were conducted in the United

States, Europe, and Australia) reported overall rates between 5.9% and 22.5%.

In contrast, studies using structured diagnostic assessments have found that 20% to 40% of psychiatric outpatients and about 50% of psychiatric inpatients meet criteria for a personality disorder. Even in primary care settings, Patricia R. Casey and Peter Tyrer found that about a third of people attending general practitioners (GPs) have a personality disorder. The vast majority of patients were not presenting for personality difficulties, but presented as problematic medical patients. Cluster C PDs are the most common PDs encountered in primary care settings. The tendency of personality disorders to co-occur with other psychiatric (and physical) diagnoses likely contributes to the discrepancy between community and patient estimates.

The most frequent personality disorders in community samples are dependent, borderline, schizotypal, and obsessive-compulsive PDs, whereas the least common are schizoid and avoidant PDs. In clinical samples, however, individuals with avoidant PD can be found frequently, as can those with most other PDs. Notably, individuals with schizoid PD are not found frequently in samples, probably because of the low prevalence of schizoid PD in the community and the ego-syntonic nature of its symptoms. It is important to note that personality disorders associated with more severe impairment or with disrupted social behavior (for example, schizotypal, paranoid, or antisocial PDs) often prompt inpatient care or intensive treatment in other settings, such as substance abuse treatment facilities.

Comorbidity is high between personality disorders and Axis I disorders as well as among personality disorders themselves, a fact that is generally considered problematic for the validity of the *DSM-IV* personality disorder diagnoses. In Cluster A, up to two-thirds of patients with paranoid PD in clinical samples meet criteria for another PD, most frequently the schizotypal, narcissistic, borderline, or avoidant PD. Paranoid PD co-occurs somewhat less frequently with Axis I disorders than do other PDs. Schizoid PD is consistently comorbid with schizotypal and avoidant PDs. Schizotypal PD is frequently comorbid with eating disorders and psychotic disorders on Axis I, and with borderline, avoidant, paranoid, and schizoid PDs on Axis II. In fact, Maria Grazia Marinangeli and colleagues estimated that schizotypal PD is the most frequently co-occurring PD, as it was significantly comorbid with all PDs except for avoidant and dependent in their study.

Within Cluster B, antisocial PD is frequently comorbid with borderline, narcissistic, histrionic, and schizotypal PDs. On Axis I, research has demonstrated that antisocial PD has a particularly strong association with substance use disorders. Borderline PD co-occurs consistently with antisocial PD; Marinangeli and colleagues found five Axis II disorders to be significantly comorbid with borderline PD. On Axis I, borderline PD frequently occurs alongside mood disorders and panic disorder. Histrionic PD is consistently comorbid with borderline and narcissistic PDs. Some studies have also found histrionic PD to co-occur substantially with antisocial and dependent PDs.

Cluster C disorders also show extensive patterns of comorbidity. Avoidant PD is often comorbid with dependent PD on Axis II, and with mood, anxiety, and eating disorders on Axis I. Dependent PD is substantially comorbid with mood, anxiety, and psychotic disorders on Axis I, and with borderline and avoidant PDs on Axis II. Dependent PD is also frequently comorbid with paranoid PD and obsessive-compulsive PD. The results of studies on the comorbidity of obsessive-compulsive PD (OCPD) with other disorders are inconsistent. The majority of patients with obsessive-compulsive disorder (OCD) do not meet criteria for OCPD. Further, for those with OCD with concurrent PD diagnosis, OCPD occurs no more frequently than any other PD.

### Course and Prognosis

PDs are thought to have an onset in late adolescence or early adulthood and are assumed to persist throughout the life span, although there is a relative paucity of empirical evidence to support these notions. Recent research suggests that personality can change significantly over time, and PDs might not be as temporally stable as once thought. However, research also indicates that different PDs have different levels of stability across the life span.

Generally, research has demonstrated that people with Cluster A disorders do not typically improve significantly over time; however, some treatment gains have been documented for persons with schizotypal PD. There is evidence that many patients with antisocial and borderline PDs recover as they grow older, although they typically continue to experience severe interpersonal dysfunction and other forms of

psychopathology. Narcissistic PD may also remit with age. Research has generally shown, however, that individuals with Cluster C disorders do not tend to recover as they age.

### Treatment Implications

Although patients with PDs are notoriously difficult to treat, a meta-analysis conducted by J. Christopher Perry and his colleagues suggested that psychotherapy is an effective treatment for PDs. Psychotherapy is associated with a rate of recovery that is seven times faster than the recovery rate typically observed when psychotherapy is not received. In general, longer treatments yielded greater effect sizes. Effect sizes in a meta-analysis indicate the overall strength of an effect. For example, an effect size of 0.8 would be considered large. Another recent meta-analysis by Falk Leichsenring and Eric Leibling found that psychodynamic therapy yielded a large overall effect size of 1.46, with effect sizes of 1.08 for self-report measures and 1.79 for observer-rated measures. This contrasted with cognitive-behavioral therapy, in which the corresponding effect sizes were 1.00, 1.20, and 0.87, respectively. However, such studies are difficult to interpret because the studies differ, even within the same therapy group, in terms of therapy content, patient diagnosis, length of treatments, outcome assessments, and other variables.

To date, there have been no controlled or uncontrolled outcome studies for histrionic, dependent, schizotypal, schizoid, narcissistic, passive-aggressive, or paranoid PDs. However, a number of studies have used samples that included a mixture of PDs, usually excluding patients with BPD. Although these studies generally show improvement in treated patients, particularly with the brief psychodynamic treatments, these studies are difficult to interpret in terms of specific PDs because they do not denote specific diagnostic cohorts.

There are a number of controlled studies for avoidant PD. Overall, these studies suggest that improvements can be found with treatments that employ social skills training alone or in combination with exposure and cognitive techniques; however, many patients did not show clinically significant improvement or generalization to other contexts. Several studies have examined particular treatments for Cluster C PDs with mixed results. The majority of psychotherapy outcome research for PDs has focused on borderline PD. A number of therapies

have received empirical support, including psychoanalytically oriented partial hospitalization, cognitive therapy, and dialectical behavior therapy.

There is strong evidence that the presence of PDs negatively affects the outcome of treatment for various Axis I disorders, such as major depression, anxiety, posttraumatic stress disorder, eating disorders, substance use disorders, and bipolar disorder. Given these findings, clinicians who consider Axis I mood disorder diagnoses or anxiety disorder diagnoses to be primary and PDs to be less relevant for treatment planning may be seriously mistaken.

PDs are highly prevalent, extensively comorbid with other psychiatric disorders, and difficult to treat. Although there are studies supporting the treatment efficacy for specific PDs, such as borderline PD and avoidant PD, many studies are difficult to interpret because they studied samples with mixed PDs. At present, the most conclusive evidence exists for cognitive-behavioral and psychodynamic treatments for borderline PD, behavioral treatment of avoidant PD, psychodynamic and cognitive therapy treatments for Cluster C disorders, psychodynamic treatment for mixed PDs, and supportive-expressive psychotherapy for opiate-addicted antisocial patients. Little, however, is known about the specific mechanisms of action in these treatments. Anthony Bateman and Peter Fonagy have suggested that common mechanisms of action to most tested treatments for PDs may include the provision of a coherent model in the context of a well-structured treatment, focused efforts at compliance to the treatment and connection with the therapist, and the explicit targeting of problematic symptoms.

## PERSONALITY THEORIES

---

Personality theories attempt to identify personal characteristics people share and to determine the factors that produce their unique expression by any given person. Sigmund Freud developed the first theory of personality, *psychoanalysis*, from his profound insight that emerged in the early 1890s as he treated patients with neurotic disorders: forces that exist in the unconscious determine human behavior. Over the next 40 years he formulated the most influential personality theory in the 20th century. Freud argued that people's behavior reflects the outcome of a lifelong struggle in which repressed unacceptable sexual and aggressive instincts in the id are redirected toward acceptable expression by the forces of reason in the ego and of conscience in the superego. These instincts sustain the self throughout life, at the cost, however, of directing aggression toward others.

Freud's ideas attracted numerous young European intellectuals in the early 20th century, the most prominent being Carl Jung and Alfred Adler. Both departed from his orthodoxy to develop their own theories, *analytical psychology* and *individual psychology*, respectively. Jung partitioned the psyche, as he called the mind, into the conscious ego, the personal unconscious, and the collective unconscious. He posited that inherent in each person is a lifelong process of individuation during which differentiation from others and a balancing of the opposing forces of the psyche (e.g., rationality/irrationality, masculinity/femininity) are sought. If attained, an integrated self emerges.

Adler reasoned that each individual struggles throughout life to overcome feelings of inferiority that

arise during the first few years of life as the child, helpless and completely dependent, compares itself to its more capable caretakers. The child responds to these feelings unconsciously by striving for superiority (personal competence), formulating rudimentary life goals that give this striving a focus, and structuring a style of life to attain these goals.

The ego, according to Freud, has no independent functions. It acts only as a mediator to satisfy the instinctual demands of the id. Freud's daughter, Anna, and Margaret Mahler expanded the concept of the ego in the mid-20th century to include functions that guide the person's competence in mastering life's demands, particularly those related to social interactions. Their work focused on the study and treatment of children and gave rise to *psychoanalytic ego psychology*.

Erik Erikson elaborated this concept further in the second half of the 20th century. He postulated that ego development is bound closely to changing social institutions and values. Central to his theory is the development of ego identity, a process that begins in adolescence and continues throughout life. Erikson reasoned that ego development occurs via a series of genetically predetermined stages (critical periods). During each stage specific developmental crises of increasing social complexity are faced. Society ensures that the process unfolds in the proper order and at the proper pace.

*Object relations theorists* elaborated the concept of the ego and transformed core psychoanalytic concepts. Prominent among these theorists were Melanie Klein, David W. Winnicott, and Heinz Kohut. They emphasized the enduring influence of interpersonal relations on a person's unconscious processes and the impact of these relations on the development of a person's inner world, especially on the infant's interpersonal strivings for safety, love, empathy, admiration, and trust. Harry Stack Sullivan, an *interpersonal theorist*, viewed the mother's relationship with the infant as crucial to the child's developing self system. Karen Horney, a *social psychoanalytic theorist*, emphasized the critical influence of the parents on the developing child's self-images and tendencies to move away from, toward, or against others.

From the 1930s to the 1950s, John Dollard and Neal E. Miller transformed Freud's psychoanalytic concepts into the language of stimulus-response psychology. Their work, *psychodynamic social learning theory*, produced the *frustration-aggression hypothesis*, a testable behavioral hypothesis of Freud's aggression

instinct, as well as behavioral formulations of Freud's main theoretical concepts. Following in this tradition, Albert Bandura, founder of *social cognitive theory*, argued that cognitive processes, especially observational learning, not direct reinforcement, play a vital role in a person's development. His perspective on the developing individual's behavior was multicausal—a person both acts on and reacts to the environment. The person's awareness of the nature of these interactions yields a sense of personal control or perceived self-efficacy. These theoretical perspectives contrast with those of the *radical behaviorists*, John B. Watson and B. F. Skinner, whose focus was on observable behaviors, reinforcement contingencies, and the reinforcement history that shaped the constellation of behaviors characteristic of any given individual.

A dramatically different perspective offered by the *humanistic self-actualization theorists* Abraham Maslow and Carl Rogers emphasized the process of personal self-growth. Central to Maslow's theory is a hierarchy of needs that ascends from basic needs (physiological, safety, belongingness and love, and esteem) to the highest need (self-actualization). The need for self-actualization guides the person toward truth, beauty, knowledge, justice, and unity. Rogers emphasized the person's subjective experience, the importance of personal freedom and choice, and the self-actualizing nature of human motivation. The actualizing tendency is undermined when parents' love is conditional upon the child behaving in approved ways. Conditional love produces an incongruity between the real self (the person's actual core experience) and the perceived self (the self-image), fostering unhealthy personality development.

Rollo May's *existential phenomenological psychoanalysis* shares a kinship with both the humanistic and psychoanalytic perspectives. He stressed the ongoing, continuously becoming aspects of human personality, human freedom, creativity and self-affirmation, the human capacity to interpret reality in ways to impart meaning to life, and the ultimate responsibility humans have for creating their own lives. Like Rogers and May, the *personal construct theory* of George A. Kelly considered subjective interpretations of reality as critical in determining a person's behavior, making sense of life, and developing ways in which to anticipate future events.

Historians of psychology trace the beginning of scientific inquiry in personality to the publication of Gordon Allport's *Personality: A Psychological*

*Interpretation* in 1937. Allport, the father of *trait theory*, unlike the other pioneering theorists, was a scientist, not a clinician. His research indicated that all people possess broad predispositions that cause them to behave in consistent ways across diverse situations and time. These traits give rise to behaviors that express them, and influence people's subjective experience. Allport viewed traits as real entities that exist inside a person to form an overlapping, interrelated network. They are distributed among all people, but are expressed uniquely by any given person. Development of a person's unique configuration of traits follows a path characterized by seeking a sense of purpose in life and coming to know the self.

Hans Eysenck, a *biosocial theorist*, used factor analysis to identify clusters of traits that formed three personality dimensions (neuroticism, extraversion, and psychoticism). His research revealed performance differences between individuals on laboratory tests (conditioning, motor skills, vigilance) of these dimensions that reflect variations in central nervous system (CNS) arousal. He theorized that the CNS is the primary source of human personality and that the three personality dimensions are phenotypic expressions of genotypic variations in the ascending reticular activating system or the subcortical brain structures of the limbic system and hypothalamus.

The pioneers in *personality theory* were grand theorists whose theoretical formulations, with Allport and Eysenck the exceptions, derived from clinical observations not from experimental studies. As such, these theories were built largely on principles that could not be tested or refuted. In the last half of the 20th century a widely accepted, scientifically based theory of personality emerged from factor analytic studies. The five-factor (or Big Five) model originated from research by several investigators, including a single publication in 1934 by Louis L. Thurstone, a series of investigations by Raymond B. Cattell in the 1940s, and another single publication in 1949 by Donald Fiske. Thurstone, a pioneer in the development of *factor analysis*, reported that five independent factors were identified in the ratings of 1300 raters who selected personal adjectives from among a list of 60 that described a person they knew well. Fiske also found five factors in an analysis of a set of 22 variables developed by Cattell. Indeed, work in the last half of the 20th century by Ernest C. Tupes, Raymond E. Christal, John M. Digman, Lewis R. Goldberg, Paul T. Costa, Jr., and Robert R. McCrae has consistently identified five broad categories of

human traits: Extraversion, Neuroticism, Conscientiousness, Agreeableness, and Openness to Experience (also called Intellect).

The study of personality across the last 120 years has produced an array of conceptual models that has enriched our understanding of human behavior. These models construe personality in radically different and seemingly inconsistent ways. In the first decade of the 21st century, however, Dan P. McAdams and Jennifer L. Pals proposed a model for integrating these divergent concepts into a coherent view of personality. Their conceptual framework of the general and unique aspects of human behavior is based on five principles. First, human nature is best explained by evolutionary theory, which provides the first principles for a scientific understanding of psychological individuality. Second, variations in a small set of broad dispositional traits, like those enumerated by the Big Five model, provide the most stable and recognizable aspects of psychological individuality. They represent the most common states individuals experience across situations and time. Third, characteristic adaptations in response to everyday social demands that may change dramatically over time account for the situation-specific behaviors of individuals not explained by traits. Fourth, integrative life narratives that individuals construct to give culturally linked meaning and identity to their lives further influence individual behavior. These narratives, essential for psychological growth and well-being, differentiate one person from all other persons. Finally, culture has its most profound impact on individual life narratives. An individual's cultural context determines the characteristic adaptations that will express any given trait, and account for individual uniqueness.

This new conceptual framework holds forth the promise of distilling the complexities of human nature into their fundamental essence, thereby allowing the scientific description of personality to avoid the hopeless complexity of past efforts.

## PERSONALITY THEORIES, BEHAVIORAL

Traditional models of behaviorism, represented by figures like John B. Watson and B. F. Skinner, are typically considered inconsistent with the concept of “personality,” which itself represents an unobservable construct. Such “radical” behavioral approaches emphasized the study of observable behavior, and thus any theory of personality was restricted to typical patterns of behavior exhibited by a particular individual based on his or her reinforcement history. More recently, and with the proliferation of behavioral and cognitive-behavioral counseling approaches, newer approaches have attempted to reconcile traditional models of behaviorism with a description of human personality. Traditional behavioral principles have been translated into behavioral approaches to counseling, as well as contributing to modern cognitive-behavioral therapies.

This entry begins with a description of the fundamental approaches to learning that represent the foundation of behaviorism. Skinner's personality theory, which has evolved into the modern study of behavior analysis, follows. John Dollard and Neal Miller's attempt to reconcile behaviorism and psychoanalysis is presented next, followed by the social cognitive approach represented by Albert Bandura and Julian Rotter. That is followed by an introduction to Arthur Staats's relatively recent theory of psychological behaviorism. Finally, a rudimentary description of several techniques used in behavior therapy is provided.

## Learning Approaches

### **Classical Conditioning**

Classical conditioning, typically attributed to Ivan Pavlov, focuses on the responses of an individual to a particular stimulus in the environment. The response is considered automatic on the part of the individual, with no cognitive interpretation of the stimulus or internal debate regarding how to respond. Watson, one of the first pioneers of behaviorism, further studied this form of stimulus-response learning.

In the classical conditioning paradigm, a previously neutral stimulus comes to elicit a response by serving as a signal for another stimulus that normally elicits that response. Pavlov conditioned the response of salivation in dogs to the sound of a tone by repeatedly preceding the presentation of food with the sound of the tone. The tone, originally a neutral stimulus, became a signal for the food, and thus elicited salivation similar to the actual presentation of the food.

Later, Watson showed that even emotional responses could be subject to classical conditioning. He worked with a child known as “Little Albert,” in whom Watson was able to condition a fear response to a white rat. Moreover, this response generalized to other stimuli that were white and furry, similar to the rat.

### **Operant Conditioning**

Operant conditioning emphasizes the effects of environmental contingencies, such as rewards (or reinforcement) and punishment, on the frequency of behavior. Edward Thorndike, in his attempt to formulate a series of “Laws of Learning,” articulated operant learning through the “Law of Effect,” which states that a behavior followed by a “satisfying state of affairs” is likely to occur more frequently. Skinner originated behavior analytic theory based on operant principles, and in fact developed a comprehensive approach to personality based on these same principles. Skinner focused primarily on reinforcement, which he defined as any consequence that increases the likelihood of a response. Moreover, the schedule of reinforcement—the frequency and timing of reinforcement for a given behavior—has ramifications for the frequency of the behavior’s occurrence, and the likelihood the behavior will continue to occur in the absence of reinforcement. Extinction of a response occurs when the response is no longer elicited due to a continuing absence of reinforcement.

Operant conditioning can also promote the development of more complex behaviors through a process

called *shaping*. Shaping involves the reinforcement of successive approximations of a complex target behavior. For example, to train a dog to roll over may require first rewarding the dog for laying down, then for rolling onto one side, then for rolling onto its back, then to the other side, and finally back onto its belly. Each step of the process is an end unto itself, earning reinforcement for the individual, and then becomes only the prerequisite for the reward at the next step, until the entire series of behaviors becomes necessary for the reinforcement.

## **Skinner's Personality Theory**

Skinner proposed that human behavior is shaped by a variety of consequences. These consequences, or contingencies, may be administered by another person (a parent, teacher, spouse, or boss), or may be naturally occurring in the environment. Each consequence affects the future likelihood of that behavior. Therefore, each individual has a unique history of such contingencies, and each develops a unique repertoire of behaviors of varying likelihood.

This contingency history approach is distinct from trait theories of personality that view each individual as having a set of traits, or characteristics, that “lead to” a set of behaviors. Traditional behaviorists reject the notion that an internal and amorphous mechanism is responsible for behavior. They believe the contingency or reinforcement history determines an individual’s behavioral tendencies.

### **Development**

For Skinner, the development of these behavioral tendencies occurs through gradual exposure to contingencies within an individual’s environment. Skinner also later incorporated the idea of imitation as a means of learning. Specifically, he asserted that a child might learn a behavior through imitation of a parent or peer, but only if the child’s prior imitations had been reinforced. In other words, a child would be more likely to imitate a behavior if he or she had been previously reinforced for imitating other behaviors. This mechanism increases the individual’s repertoire of behavioral tendencies still further.

### **Psychopathology**

Skinner asserted that all of an individual’s behaviors, including pathological behaviors, are learned

through these same mechanisms. Mentally ill individuals have learned a maladaptive response that leads to aversive consequences for the individual or for others because that response has been, and may continue to be, reinforced. In addition, an individual may have been unable to learn an appropriate response to a certain situation or stimulus, due to inadequate reinforcement, or due to never having performed the skill in a way that was reinforced.

## Walden Two

Skinner explored the hypothetical application of the principles of contingency management to an entire culture in his classic book *Walden Two*, published in 1948. In *Walden Two*, Skinner used this process of “cultural engineering” to create an idealized community in which crime, unemployment, and wars are a thing of the past. Skinner argued that such a society would be feasible in America, and it would solve societal problems if truly employed.

## Behavior Analysis

Modern behavior analysis is predicated on Skinner’s work. Behavior analytic theorists share Skinner’s emphasis on an individual’s reinforcement history as the determinant of his or her behavioral tendencies. The concept of personality implies a certain degree of consistency in an individual’s behavior; thus, behavior analysis posits that consistent behavioral tendencies are the result of consistent contingencies across similar situations over time, and across different situations.

The lack of consistent contingencies would lead to more unpredictable behavior. A lack of consistency in responding is a sign of a lack of stability in an individual’s “personality,” and thus of some degree of pathology. Behavior analysts advocate adjustments in contingencies as a means for individuals to “relearn” adaptive and more consistent ways of responding.

## Human Nature

Both Skinner and the behavior analytic view that ensues from his theory share certain assumptions and positions regarding dimensions of human nature. Among these are an emphasis on environmental influences and a deterministic view of behavior. While Skinner was not as radical as Watson, he did believe that environmental influences (“nurture”) could override

biological processes (“nature”). Behavior analysts share this belief. The element distinguishing the view of many behaviorists from other theorists is their belief that biological processes, while very important, are less observable than environmental influences, and thus less subject to measurement.

On the question of free will, Skinner did assert that humans have the power of self-control (i.e., free will), or the ability to manipulate their environment to manage their own behavior. Skinner’s position implies a bit more self-determination than the purely stimulus-response learning emphasized by Watson, but he maintained that even this process requires external contingencies. In sum, Skinner and the behavior analysts in general have leaned heavily toward the position that most human behavior is determined by environmental contingencies.

## Dollard and Miller’s Theory

Dollard and Miller attempted to reconcile the conflicting ideas in behavioral and psychoanalytic theories by reformulating Freudian concepts in behavioral terms. They relied heavily on Clark Hull’s concepts of habits and drives. Habits are connections between stimuli and responses. Drives are aversive stimuli that impel a behavior. The ensuing behavior reduces the drive and is thus negatively reinforced. In a departure from the more radical behaviorism of Watson, Dollard and Miller suggested that drives can be either external (such as a need for money or a diploma) or internal (such as hunger or loneliness), thereby introducing the idea that even nonobservable elements may be included in a behavioral theory.

Dollard and Miller further suggested that certain stimuli in the environment serve as cues—consistent with what Skinner called discriminative stimuli—that determine where and when a behavior will occur. Each cue may prompt a range of potential behaviors. These potential behaviors form a response hierarchy based on the relative likelihood of each response in that situation. Each potential response’s position in the response hierarchy is effected in part by the individual’s particular drives when the cue is present. The changing of response probabilities due to differing situations is what Dollard and Miller consider the process of learning.

## Conflict

Freud’s psychoanalytic theory focuses heavily on intrapsychic conflict. Dollard and Miller studied

conflict as it pertains to response hierarchies. They suggested that each type of conflict represents choices between goals. An approach-approach conflict occurs when an individual must choose between two equally desirable goals. These goals may conflict because the individual has two competing drives, such as choosing between studying for a test or going out with friends. An avoidance-avoidance conflict occurs when the individual must choose between two undesirable outcomes, such as studying for an exam or failing. An approach-avoidance conflict involves a single response that has both a desirable and an undesirable outcome, such as working at a high-paying but unpleasant job. Finally, in a double approach-avoidance conflict, the individual has to choose between two different responses, each of which has both a desirable and an undesirable outcome. For example, a job applicant may have to choose between the high-paying but unfulfilling job and a lesser-paying but more interesting position.

Like Freud, who claimed that neurosis could result from inadequate resolution of conflicts, Dollard and Miller suggested that pathology could ensue if the individual has difficulty with these conflicts. For example, some individuals may become immobilized by conflict or choose to escape the decision by maladaptive means.

### ***Frustration and Aggression***

Dollard and Miller first formulated the frustration-aggression hypothesis in 1939. They asserted that frustration, which occurs when there is unexpected interference with a goal-directed response, is always the cause of aggression. Generally, the more frustrated the individual, the greater the amount of aggression he or she will express. This approach mirrored Freud's position that aggression serves as a cathartic release of tension.

Also consistent with Freud's theory was Dollard and Miller's work on displaced aggression. Specifically, they agreed that individuals who are unable to respond to the original stimulus will respond to the most similar available stimulus. For example, if your boss makes you work late on an evening when you had other plans, you may not express aggression toward your boss because of a fear of punishment. Instead, you will express aggression toward someone who is in some way similar to your boss when the opportunity (cue) occurs.

### ***Critical Training Periods***

Dollard and Miller attempted to convert Freudian developmental stages into more behavioral terms. The result was what they called critical training periods. Three of the four training periods mirror Freudian psychosexual stages of development, and are thought to affect personality development. The feeding situation, which roughly corresponds to the Freudian oral stage, involves stimulus generalization; infants who learn that their hunger drive will be alleviated by others develop the belief that they will be able to satisfy their other drives. Moreover, in this training situation, the infant may develop secondary drives learned through association with these primary drives. For example, the drive of intimacy may be developed through the close, comfortable relationship between infants and their mothers during feeding.

The cleanliness situation, akin to Freud's anal stage, involves a similar emphasis on toilet training. Difficulty during toilet training may be met by parental disapproval and punishment. The child may interpret the disapproval as focused on themselves rather than their behavior, and thus develop anxiety. This anxiety may generalize to other situations in which developing persons perceive themselves as inadequate or unlovable.

Dollard and Miller suggested that early sex training, corresponding to Freud's phallic stage, involves anxiety associated with initial expressions of sexuality and sexual behavior. Specifically, behaviors such as masturbation are typically called dirty, perverted, or wrong. Again, this association may be generalized to other sexual behaviors, and to fulfillment of the sexual drive overall.

Finally, Dollard and Miller asserted that a child who becomes frustrated may become angry and aggressive. Aggressive behaviors by children are typically met with some form of punishment. The result is an approach-avoidance conflict because the child who experiences frustration must either express that anger and get punished or suppress the anger. Chronic suppression of anger may ultimately lead to development as a passive, unassertive adult.

### **Social Cognitive Theories**

Traditional behavioral approaches have eschewed the cognitive processes that occur within humans as being unobservable. Theorists from this perspective have as

a whole believed not that these processes are insignificant but simply that they are not measurable, and thus not subject to scientific inquiry. Social cognitive and social learning approaches are based on many of the same principles as behavioral theories, but include the cognitive element that behaviorists have omitted. The primary figures associated with this approach are Julian Rotter, Walter Mischel, and Albert Bandura.

### **Reciprocal Determinism**

Social-cognitive theory and its distinction from purely behavioral theories are exemplified by Bandura's concept of reciprocal determinism. Bandura posited that behavior, the environment, and the cognitive processes within an individual have a mutually interactive relationship. Instead of a unidirectional stimulus-response relationship, these three variables all affect one another.

These cognitive processes are what Mischel called *person variables*. Generally, social cognitive theorists de-emphasize traits, which imply greater stability across situations, in favor of the processes that enable individuals to adapt to specific environmental conditions and circumstances. An individual's competencies involve what he or she is capable of doing. Encoding strategies reflect how an individual cognitively represents information. The individual also has expectancies regarding how likely he or she believes an action will result in a particular outcome. Such outcomes will each have a particular subjective value assigned by the individual. Finally, the individual engages in a self-regulatory process that includes planning an action or series of actions, executing those actions, and adjusting the actions as he or she evaluates the progress made toward the goal.

Bandura also described the variable of self-efficacy, or the individual's perception of his or her ability to perform a behavior in a given situation. Self-efficacy can be considered to be general, such as an overall confidence in one's ability to perform actions as needed. More specifically, however, self-efficacy refers to confidence in a specific situation. For example, an individual may feel comfortable sitting at home answering questions to a television quiz show; the individual's confidence in his or her ability to do so in front of an audience and cameras with prize money on the line may be different.

Rotter is best known for his work on the concept of locus of control, or the explanation an individual has for events and outcomes. Persons who attribute

outcomes to factors outside themselves (e.g., luck, divine providence, or another person) have an external locus of control. Those who attribute outcomes to their own efforts or abilities have an internal locus of control. Generally, having an external locus of control is associated with poorer psychological and physical health.

### **Vicarious Learning**

Another distinction between the social cognitive approach and purely behavioral models of personality is the stipulation that learning can occur without a direct experience of classical or operant conditioning. The process can happen vicariously, according to social learning theorists, and imitation need not be reinforced for observational learning to occur.

Bandura is perhaps best known for his work on observational learning (i.e., learning by watching behavior). His Bobo Doll experiments showed that children could learn aggressive play behaviors by watching an adult model such behaviors against a blow-up clown doll. Examples of observational learning are evident whenever an individual learns how to cook a meal by watching a cooking show, learns how to change a flat tire by watching a mechanic, or is persuaded to buy a product by a celebrity on a television commercial.

Both classical and operant conditioning can occur by observation. Vicarious conditioning occurs when an individual becomes conditioned to a stimulus by viewing another individual being conditioned to that same stimulus. Vicarious reinforcement occurs when an individual becomes more likely to engage in a behavior after seeing someone else rewarded for that behavior.

### **Pathology**

According to the social cognitive view, most pathology results from dysfunctional expectancies. An individual may, to a maladaptive extent, overestimate or underestimate the likelihood of a particular outcome of a behavior. For example, a shy person may avoid social gatherings for fear of rejection or embarrassment, or a shoplifter may believe that he or she will never be caught and arrested.

Consistent with other behavioral theories, social cognitive theory posits that maladaptive behaviors and appropriate behaviors result from similar learning processes. We may learn appropriate behaviors through vicarious reinforcement, but we can also learn maladaptive behaviors through vicarious reinforcement

(i.e., seeing someone else run a red light successfully, and then doing so as well).

## **Psychological Behaviorism**

In recent years, Staats has criticized traditional behaviorism's emphasis on learning principles that apply to animals. He regards these principles as insufficient to explain human behavior. Staats's psychological behaviorism is predicated on the notion that humans learn new behaviors in the context of previously learned behavioral repertoires.

Staats has stated that individuals develop basic behavioral repertoires (BBRs) that facilitate later learning. Personality is the individual's combination of basic behavioral repertoires. These initial BBRs are learned through the interaction of stimulus events and the individual's sensory and perceptual processes.

Like traditional behavioral theorists, Staats has asserted that personality develops and changes through a series of learning experiences. But psychological behaviorism emphasizes the context of the individual's prior learning. Specifically, individuals develop BBRs based on their experiences with environmental stimuli. Their biological condition at the time of this learning plays an important mediating role. Later, individuals' biological conditions may be different, thus affecting their BBR, when a second stimulus event is experienced and prompts a behavior. This process demonstrates both the situational nature of behavior and the more generalized nature of personality. While somewhat stable, the BBRs can be modified or supplemented through later learning, thus reflecting the adaptability of human personality.

## **Behavior Therapy**

Behavior therapy involves the use of learning principles to modify maladaptive behaviors. Behavior therapy focuses on the acquisition of necessary skills to obtain reinforcement (such as in social skills training), the learning of more adaptive responses to environmental stimuli (as in systematic desensitization), and the modification of environmental factors to promote adaptive behaviors (as in contingency management).

### ***Social Skills Training***

Social skills training is used to promote adaptive interpersonal behaviors to facilitate the acquisition of social reinforcement. Therapy clients reporting loneliness,

depression, or anxiety may have inadequately developed skills to promote satisfactory interpersonal relationships. These individuals do not engage in appropriate eye contact, facial expressions, tone of voice, and other conversational skills, many of which are more typically learned in the natural environment. In therapy, clients may engage in role-play activities where the therapist first models the appropriate skills, and then encourages the client to demonstrate. Real-world assignments to test these new skills are instrumental in helping clients to apply these skills to genuine situations and to gain genuine social reinforcement.

### ***Systematic Desensitization***

Systematic desensitization is most applicable to situations in which an individual experiences a disproportionate or dysfunctional level of anxiety to a stimulus or situation. The process relies on counterconditioning (i.e., the development of a response—relaxation—that is incompatible with anxiety). During relaxation training, clients are taught a series of exercises to relax the mind and body. Relaxation training may involve imagery (i.e., teaching clients to picture themselves in a tranquil, placid scene). Clients also develop a hierarchy of fear-inducing situations, and rank them according to the level of anxiety they cause.

Once a client has become adept at relaxation and has completed the hierarchy, the therapist leads the clients through each step in the hierarchy. The client attempts to maintain the relaxation response in the context of each situation on the list. This process may occur through imagery or in real-life exposure.

### ***Contingency Management***

Contingency management entails the manipulation of reinforcement and punishment to increase the frequency of desirable and adaptive behavior. This approach can use simple contingency plans, such as rewarding a child with a cookie for eating his or her dinner, or more complex point systems or token economies, such as those used in many schools and institutions. Withdrawal of reinforcement through time-out is also a form of contingency management.

## **Relevance**

Behavioral approaches to personality began with the radical behavioral approach of Watson, which was largely incompatible with an internal, nonobservable

construct such as personality, but they have evolved over time. Skinner's behavior analysis is still relevant, as are more modern approaches such as Staats's psychological behaviorism, which is largely consistent with those earlier approaches. Behavioral approaches provide the theoretical foundation for the wealth of effective techniques that today are used as part of a behavioral approach to counseling.

## PERSONALITY THEORIES, COGNITIVE

Cognitive theories of personality focus on the processes of information encoding and retrieval, and the role of expectations, motives, goals, and beliefs in the development of stable personality characteristics. This approach differs from personality theories that emphasize either the conditions within which personality develops (e.g., behavioral theories) or the trait structures that are revealed in those various conditions (e.g., evolutionary and trait theories). As such, cognitive theories of personality are particularly relevant for counseling psychology because of their core assumption that lasting personality change can occur as a result of rational analysis and insight.

Personality theories are often categorized as either *nomothetic* (i.e., personality is understood in terms of an individual having greater or lesser amounts of traits that are common to all people) or *idiographic* (i.e., each individual has a unique personality structure and may possess traits that others do not possess). Taking a nomothetic approach, a personality theory can be used to generalize about an individual or to categorize the person. For example, a person can be said to have a particular trait or style. On the other hand, personality theories that take an idiographic approach attempt to describe the specific individual in such a way as to show how this one individual is different from all other individuals. Cognitive theories of personality are both nomothetic and idiographic. Nomothetic theorists have demarcated dimensions of individual difference such as cognitive styles. Idiographic theorists have developed complex descriptions of individuals cognitively embedded within their own life contexts.

### General Components of Cognitive Personality Theories

Most cognitive theories of personality focus on the ways in which personal knowledge and judgment are developed. Often this development occurs in a distorted fashion because it is necessary for people to adapt to their environment. Humans desire to be consistent in their beliefs and behaviors so that they can

predict the outcome of their actions. They are also motivated to gain social approval from others and to enhance their perception of themselves. This can result from a process of comparing one's self with those of others or a process of comparing what one believes is one's actual self with an imagined ideal self. Cognitive personality theorists have focused their efforts on describing the development of cognitions that explain the world and the individual's concept of self in it, and they have also developed some understanding of variations in cognitive styles that predict individual differences.

## History

Early ideas related to cognitive theory can be traced back to the Greek Stoic Epictetus, who claimed that processes of rational judgment were at the basis of all emotion, be it happiness or suffering. He stated that events in and of themselves have no moral or ethical meaning. Moral judgment and choice are the consequences of how people come to interpret and understand events.

At the turn of the 20th century, William James championed the idea that no psychological theory is complete that does not allow for a mechanism by which thought will regulate actions. James emphasized the role of the focus of attention in determining behavior. He also anticipated the concept of cognitive schemata by characterizing the stream of consciousness as anticipating and adapting to current events by comparing current experiences to past experiences.

Early work in social cognition forms a basis of current cognitive personality theory. Fritz Heider, an early social psychologist, emphasized that people act with others on the basis of their conceptions of themselves and of others. Heider developed the notion of *phenomenal causality*, which is the perception of causality that leads to judgment and action. Heider's ideas led to the development of the field within social psychology known as *attribution theory*, which is the study of the determinants of phenomenal causality or causal attributions. One important dimension of causal attributions is that of internal (or dispositional) versus external (or situational) attributions. People's judgments and conceptions of an event are largely determined by their beliefs regarding whether people act according to internal dispositions or because of situational pressure. Heider's ideas are often called *naïve psychology* in that the person is described as

acting according to his or her own personal theory of psychology regarding others.

## Kelly's Theory of Personal Constructs

George A. Kelly's theory of personal constructs is most frequently cited as the first modern cognitive personality theory. Kelly proposed and elaborated upon the metaphor of "person as scientist." Drawing on the theories of Heider and attribution researchers, Kelly proposed that people use observations to develop beliefs about themselves and their world. These observations are organized into *personal constructs*, which were described by Kelly in terms very similar to the current concept of cognitive schemata. Cognitive schemata are meaningful organizations of related pieces of knowledge. Kelly proposed that people make predictions and interpretations regarding their experience on the basis of their personal constructs (or *schemata*), and they endeavor to behave in a manner that is consistent with their personal constructs.

Kelly proposed that personal constructs develop and change through processes that are similar to assimilation and accommodation. As described by the cognitive developmental theorist Jean Piaget, assimilation is the process by which people integrate new information into the existing body of information they already possess. Accommodation is the process by which people change or modify their existing knowledge based on the information gained from new experiences. Like Piaget, Kelly viewed cognitive development as a continuing interplay between assimilation and accommodation. For example, children learn to catch a large ball by holding out their arms a certain distance apart as the ball is thrown. Later, when a smaller ball is thrown, they will hold out their arms the same distance apart (assimilation) but fail to catch the ball. They will need to accommodate the new information that the size of the ball must determine the distance apart that they spread their arms (i.e., their catching schema).

Kelly proposed that individuals are motivated to maintain a hierarchical structure of personal constructs that is consistent with the world, as they perceive it. Anxiety results when information does not conform to the expectations generated by their constructs. This leads to a need to change or reorganize their cognitive structure (accommodation), or to force the discordant experience to fit their preexisting construct hierarchy (assimilation). Often assimilation

requires less cognitive effort than accommodation. Rigidly adhering to assimilation via “obsolete” constructs by refusing to expend the effort to accommodate, or being unable to accommodate, can lead to irrational behavior.

### ***Locus of Control***

Julian Rotter developed a social learning theory that emphasized the role of the cognitive expectancy of reward in determining behavior. The major contribution of this theory to the psychology of personality was the proposal of a generalized cognitive expectancy that Rotter called *locus of control*. Individuals differ to the extent that they generally believe their own actions are related to personal outcomes. Those with an *internal* locus of control have a strong expectation that success or failure will result from their own efforts. Those with an *external* locus of control generally believe that success or failure is determined by fate, chance, or the will of others.

Currently, psychologists believe individuals can have different locus of control beliefs for different aspects of their life. For example, an individual could have an internal locus of control regarding social relationships and an external locus of control regarding his or her health. One domain that has been predictive of therapy outcome is the individual's locus of control beliefs concerning illness or health outcomes. Causal attributions also determine whether events are believed to be stable or transient. For example, a stable causal attribution might be, “I did poorly on the algebra test because I have never been very good at math.” A transient attribution could be, “I did poorly on the algebra test because I did not get enough sleep last night.” Finally, causal attributions may be general (i.e., relevant to many experiences) or specific (i.e., applicable only to a single instance). For example, a stable causal attribution might be, “I didn't dance well because I have never been coordinated.” A specific attribution could be, “I didn't dance well because I have never liked dancing.”

### ***Cognitive Style***

Herman A. Witkin observed that individuals differ in their general modes of intellectual and perceptual functioning along a number of dimensions. Some of the dimensions that have been shown to be useful predictors of individual differences are tolerance for ambiguity, impulsivity versus reflectivity, field dependence

versus field independence, cognitive complexity versus simplicity, and the more motivational “need for cognition.” Tolerance for ambiguity relates to open- versus close-mindedness and the ability and individuals' willingness to accommodate their schemata to new experience. Impulsivity versus reflectivity refers to the extent to which one will consider consequences of acts and alternatives before acting. Field dependence versus independence refers to a global as opposed to analytic style of perceiving. Field-dependent perceptions are influenced by the context within which they occur. Field-independent perceptions are more analytical and somewhat independent of the context within which they occur. Cognitive complexity versus simplicity refers to the usual number of interrelated schemata that are applied to experiences. Need for cognition refers to individual differences in the desire to be challenged to think and reflect. It is currently believed that many of these dimensions along which individuals differ are genetically based or at least congenital and somewhat difficult to modify.

### ***Bandura's Social Cognitive Theory***

Albert Bandura expanded cognitive personality theory by describing processes of observational or vicarious learning and the role of belief structures such as self-efficacy. Bandura agreed that people develop and change as a consequence of the direct rewards and punishments they receive from the environment. These rewards and punishments occur as a consequence of their actions (the basis of operant conditioning). However, we also learn by observing others (models) and noting the consequences that result from their behavior.

The study of observational learning led psychologists to distinguish between the factors that influence the vicarious acquisition of knowledge and the factors that influence the actual performance of some behavior. Among the factors that influence the vicarious acquisition of knowledge are the strength and valence (i.e., emotional value) of the observed consequences of the behavior, the similarity of the model (i.e., person performing or demonstrating the action) to the observer, and the social status of the model. In contrast, the person's self-efficacy beliefs influence the actual performance of some behavior. *Self-efficacy* is a person's beliefs regarding what should be done to achieve a desired goal, and the person's beliefs regarding his or her ability to perform those actions.

The first set of beliefs relates to the individual's locus of control expectancies, but by themselves these beliefs will not determine whether the goal-seeking behavior will be performed. The critical factor is the individual's beliefs regarding his or her ability to perform the necessary behavior successfully.

Self-efficacy beliefs depend on a number of factors, including previous direct experience, observational learning, social persuasion, and self-assessment and interpretation of current and past emotional states. Conditions that lead to the development of healthy self-efficacy include the positive factors of family interactions (warmth, support, and challenge), and peer networks (similar models, access to activities, and social motivation), as well as negative factors such as competition and stress. Like locus of control, self-efficacy is largely domain specific (e.g., academic self-efficacy, social self-efficacy, and athletic self-efficacy can all differ for a given person).

According to Bandura, a complete understanding of the person involves recognition of the reciprocal interaction of personal (cognitive and affective) factors with environmental factors. Bandura labeled this concept *reciprocal determinism*. By this he meant that personal factors can be influenced by environmental factors such as rewards, punishments, and information from models, but behavior and personal factors also cause changes in the environment and in other individuals. Because of the human ability to symbolize personal experience and to think ahead about the expected consequences of personal actions, each individual has the capability to self-reflect, leading to the potential for self-directed changes in behavior. Self-efficacy beliefs are crucial to making self-directed changes because they are most functional when they are accurate. When efficacy is high but skills are poorly developed, harm and trauma can occur. When efficacy beliefs are low, even when skill level is high, personal growth will not occur and there will be little motivation for change.

### **Mischel's Cognitive-Affective Personality System**

Explaining and predicting the consistency and inconsistency of individuals across the wide variety of situations that confront them on a daily basis is a problem for personality theory in general. Walter Mischel pointed out that personal variables such as traits and dispositions are often not by themselves as predictive of behavior as variables external to the person such as the demands of

the situation. In a somewhat selective review of the literature, Mischel concluded that personality information was predictive of only a very small percentage of the variation of behavior in situations. This argument stimulated the field of personality research to elucidate the interaction of the person within the situation as opposed to focusing on person variables.

In recent years, Mischel and colleague Yuichi Shoda have made progress in describing dynamic interactions of situations with personal variables (self-efficacy beliefs, personal goals, and emotional reactions) into an integrated theory called the *cognitive-affective personality system*. This approach recognizes that persons differ in the aspects of a situation on which they focus and in the way in which they encode a particular element of a situation. The resulting theory emphasizes the interaction of situations, encoding processes, memories, beliefs, expectancies, and behavior in a reciprocally determinative dynamic. This idiographic system can be considered a model for the most complete cognitive theory of personality. A person's cognitive existence cannot be considered independently of the current situation, the individual's past history, and his or her expectations for the future.

## **Cognition and Emotion**

Cognitive theories of personality have made important contributions to counseling and psychotherapy by demonstrating the ways in which cognition can cause or modify positive or negative emotion. Aaron T. Beck's method of *cognitive-behavioral therapy* and Albert Ellis's *rational emotive behavior therapy* both emphasize the ways in which distorted beliefs (mostly attributional beliefs) directly lead to experiences of negative emotion such as anxiety and depression. A long-standing debate concerns whether all human emotions more complex than simple sensory pleasure or pain are a result of cognitive processes or are merely congruent with them. In actuality, most cognitive theories of personality emphasize the presence of evolutionarily prepared (i.e., automatic) reactions and temperaments and the importance of the individual's perception and interpretation of his or her own biological reactions during events.

### **Self-Discrepancy Theory**

Self-discrepancy theory is a form of dissonance theory that states that people are motivated to maintain a

consistency among their self-perceptions and beliefs. The humanistic psychologist Carl Rogers proposed that incongruence between the self as experienced and the ideal self is a source of human suffering. Support for this position is buttressed by the many studies that have found successful counseling outcomes characterized by reductions in this incongruence. E. Tory Higgins incorporated ideas of expectancy into the self-discrepancy model. He demonstrated that discrepancies between people's current self-appraisals and their self-constructs as they wish to be (the ideal self) lead to feelings of dejection and depression. In contrast, discrepancies between people's current self-appraisals and how they believe others expect them to be (ought self) lead to agitation and anxiety. A number of moderators of the strength of this effect have been identified, including the amount of the discrepancy, factors that increase or decrease the salience of the discrepancy, and the importance of the discrepancy to the individual.

### ***Entity Versus Incremental Judgments of Self***

Carol Dweck has demonstrated how a person's perception of self as static or as capable of growth has dramatic effects on both emotions and motivation. Dweck distinguishes between two forms of belief that people may hold regarding their efficacy. The first, or entity view, regards any ability such as intelligence as fixed or stable. Persons taking an entity view within any domain of ability (entity theorists) will develop goals that avoid failure, are measured by absolute performance standards, and are low risk. A person can also perceive his or her efficacy incrementally. An incremental theorist regards abilities as changeable or improvable through challenge and work. Incremental theorists develop relative or mastery goals and are less motivated by fear of failure. Entity theorists are performance oriented, while incremental theorists are learning oriented. Entity theorists are more likely to be judgmental regarding themselves and others and to experience helplessness, depression, and anxiety.

## **Cognitive Personality Theory in Counseling**

Cognitive personality theory is applicable to counseling in two ways. First, psychologists perform cognitively based personality assessments in order to select the most appropriate treatment methods for an

individual client. Second, cognitive personality theories provide the theoretical underpinning for interventions designed to achieve long-standing changes in personality.

### ***Assessment***

Counselors have access to a large number of assessment devices that measure cognitive style and other cognitive individual difference dimensions beyond intelligence factors. These can be useful while thinking of the counseling experience as an educational enterprise requiring the need to assess the "learning style of the client." Motivational factors can also be assessed. For example, understanding the client's health locus of control can inform the choice of methods. Other assessment devices, developed mainly for use in cognitive-behavioral therapy, assess dysfunctional beliefs in various domains.

A large number of cognitive assessment instruments have been developed. In general, each test contains a list of self-related statements, and clients are asked the extent to which they endorse each statement as "true" or "descriptive" of them. For example, a psychologist could administer the following self-statement inventories to assess anxiety disorders: (1) the Body Sensations Questionnaire to assess perception of anxiety symptoms, (2) the Anxiety Sensitivity Questionnaire to assess dysfunctional beliefs regarding anxiety symptoms, (3) the Agoraphobic Cognitions Questionnaire to assess the presence of thoughts related to agoraphobia, or (4) the Anxious Self-Statement Questionnaire to assess self-related negative cognitions regarding personal performance. These and the many other available instruments are easy to give and to score. They can be used to inform the therapist's choice of an intervention strategy or to assess progress in treatment. Unfortunately, although most of these instruments have strong content validity (i.e., they cover most of the domain that experts believe to be relevant), they have not been subjected to the kinds of reliability and statistical stability testing that characterize other psychological tests, such as ability and achievement tests.

Other procedures that elicit the client's patterns of thoughts and beliefs are variations on the method of the Daily Record of Dysfunctional Thoughts. In this procedure, the client fills out a structured diary form reporting problematic situations and the thoughts, expectations, and beliefs that accompany his or her distress.

A more idiographic approach is necessary when assessing the person–situation interaction. There are two domains of situations that are immediately most relevant. The first involves the targeted problem situations that will be the focus of the counseling intervention. The daily diaries help to develop an assessment of the client's expectancy and belief patterns that may be problematic. Another long-standing instrument for this kind of assessment is George A. Kelly's Role Construct Repertory (Rep) test. As originally constructed, the Rep test compares and contrasts schemata regarding other individuals, but it can be modified to compare situations. Asking the client to compare groups of three concepts at a time and explain how two of the concepts are the same reveals personal constructs. This comparison, of course, reveals how the client views those two concepts as different from the third. For example, in the original Rep test, a client's best friend can be compared to the client's father and favorite teacher. In a situational Rep test, a client's most feared situation could be compared with the client's most compelling situation and most embarrassing situation.

The second situational domain to be cognitively assessed is that between the individual client and counselor. Clients enter counseling with different perceptions, beliefs, and expectations regarding therapy. These can be assessed with instruments similar to those described above. Expectations and beliefs regarding therapy have been found to be highly related to the therapeutic alliance. This, in turn, is one of the *common factors* (i.e., effective components of successful therapy) that are highly related to therapeutic outcome.

### ***Cognitive Theories of Personality Change in Counseling***

A large amount of work has been directed toward the development of methods to treat personality disorders using cognitive-behavioral therapy. Personality disorders themselves are not generally recognized as reliably identifiable entities within most established cognitive theories of personality. Nevertheless, the often successful attempts to modify long-standing patterns of living toward more adaptive and stable patterns are encouraging. The efforts indicate that therapeutic interventions that focus on changing dysfunctional beliefs can be used to modify personality. The dysfunctional beliefs that have received the most

attention include those regarding feelings of hopelessness, skill enhancement, and attitude toward treatment. Effective cognitive therapy interventions have been developed to deal with each of these issues. Furthermore, cognitive and behavioral interventions that address generalized belief structures such as self-efficacy have been used in therapy with success. The successful pairing of cognitive and behavioral techniques reinforces the view that cognitive elements of personality are best conceived as imbedded in a dynamic interaction of biological, cultural/social, and behavioral interactions.

### **Future Directions**

Cognitive theories of personality have made important contributions to psychology by explaining complex person–situation interactions, incorporating the powerful role of attributional belief systems, and delineating many of the cognitive dimensions that are critical in understanding individual differences. Nevertheless, a great deal of cognitive psychology has not yet been integrated fully into cognitive personality theories. Probably the most important oversight concerns the factors involved in decision making and choice behavior. For example, individual differences in the heuristic biases that influence decision making and many elements of the cognitive science of memory (e.g., the factors influencing retrieval bias) have not been incorporated into cognitive personality theories. The next decade will most likely see the integration of neglected areas such as these into cognitive theories of personality, just as the findings of cognitive science itself will become incorporated into comprehensive biopsychosocial personality perspectives.

## PERSONALITY THEORIES, EVOLUTIONARY

Evolutionary personality psychology suggests that human personality variation is a meaningful and relevant source of human diversity, and that different combinations of heritable personality traits biologically prepare individuals to exploit the different social niches they inhabit. Human personality variation relates to numerous important life outcomes, including life history traits such as sexuality, sociality, fertility, morbidity, and mortality. The effects of personality variation upon these fitness-relevant demographic parameters renders such variation subject to both natural and sexual selection. Furthermore, the adaptive value of any given personality trait is relative to that circumscribed portion of the environment which the individual habitually inhabits (i.e., the individual's physical and social niche), and in which the individual is functioning. Any given personality trait can be evaluated as an adaptive function or harmful dysfunction by determining its match to the particular social niche a person occupies within a particular social environment.

This entry explains the complex mix of genetic and environmental influences on human personality variation by applying a combination of the predictions of *Brunswikian evolutionary developmental theory* and *developmental plasticity theory*. This entry also considers the significance of personality disorders from the perspectives of the *mismatch hypothesis* and the *harmful dysfunction hypothesis*.

## Personality Variation

Most evolutionary personality psychologists have concluded that individual differences in personality traits are adaptive in nature and therefore the result of natural and sexual selection. Differences in personality traits allow people within human social groups to differ in the effectiveness with which they can play different roles within human societies. Personality differences are of utmost importance because humans must detect and react to the personality traits of others to successfully navigate the social landscapes in which humans reside. The individual differences seen in personality are the result of adaptation to different niches available within human social groups. This reduces competition among group members. Although some members who are similar in personality may compete for certain roles within a society, their degree of specialization means that they will not be required to compete against all group members.

For example, in our modern society, certain people who possess higher levels of intelligence, conscientiousness, and motivation (e.g., willingness to spend many years studying) may be good candidates for careers as neurosurgeons. Other individuals who possess higher levels of impulsive sensation-seeking and lower levels of neuroticism (and are thus less prone to fearfulness) might be better suited than others to become deep-sea welders. While both occupations could be considered highly stressful and highly specialized, they require different types of personality characteristics. Furthermore, even within fairly narrowly defined types of careers, different individuals will gravitate toward distinct roles and physical locations within those careers. Some people will strive to become brain surgeons in extremely prestigious hospitals, whereas others will be satisfied to hold less prestigious positions in order to be able to pursue other interests, such as spending time with family and friends. The same could be said for deep-sea welders. Although all deep-sea welders might be viewed as more risk taking than the average person in any population, some will naturally gravitate toward more dangerous jobs than others. Those more reckless and impulsive individuals might also engage in such dangerous practices as smoking cigarettes within oxygen-filled decompression chambers upon resurfacing. These are modern-day examples from Western industrial society, used here for purposes of illustration, but different roles that best suit different types of individuals can be found in any human society.

The evolution of a diversity of individual traits to fit a variety of different social niches might be ultimately due to frequency-dependent selection. Frequency-dependent selection occurs when the fitness value of any particular trait is dependent on its prevalence in the population. For example, as the number of individuals possessing a certain phenotype (i.e., the observable physical, biochemical, and behavioral characteristics of an organism) increases, the adaptive value of possessing an alternative phenotype increases. At the Thanksgiving table, the more people who prefer the white meat of the turkey, the better it is for those who prefer the dark meat, because there will be more of that available. Thus, social competition drives individuals into different social niches. Filling these alternative niches offers some release from social competition.

The variation in personality documented in nonhuman animals appears to be almost entirely confined to social species. Niche-splitting (i.e., the fragmentation of the ecological space into more specialized niches) within a species leads to character displacement (i.e., the differentiation of individual traits to adapt to these different niches). The cost of deviating from the species-typical optimum (e.g., eating the dark meat when the white meat is actually better) is compensated by the benefit of release from competition (e.g., getting all the dark meat). The result for the population is an “ideal free distribution” of alternative behavioral phenotypes in which the balance of costs and benefits are equalized among competing individuals. For example, there is a tradeoff between territory size and territory quality, where resource-rich territories are generally smaller than resource-poor territories (e.g., the same amount of money will buy less land in New York than in Arizona). The resulting dispersion of individual phenotypes away from the modal norm of response for the species will thus create bell-shaped curves along different dimensions of personality.

### Evolutionary Developmental Theory

Brunswikian evolutionary developmental theory proposes that when ecological conditions are variable over evolutionary time, natural selection favors organisms that are phenotypically flexible enough to adapt by means of learning from environmental contingencies (i.e., the potentially different consequences of the same behavior in different ecological contexts). However, according to developmental plasticity

theory, this ability depends critically on the presence of reliable and valid cues that signal which alternative phenotype it is best to adopt in that particular time, space, and ecology. When reliable and valid cues are absent, natural selection favors the production of genetically diverse individuals that possess a wider variety of the different phenotypes that might be required to fit the locally and temporally varying conditions. Because many cues are often neither completely reliable and valid nor unreliable and invalid, Brunswikian evolutionary developmental theory describes these cues as possessing an ecological validity coefficient ranging between 0 and 1.

Combining these two theories leads to the prediction that individuals will manifest both sufficient developmental plasticity and sufficient genetic diversity to collectively fill all the available niches. Human personality traits such as the Big Five personality traits (i.e., Openness to Experience, Conscientiousness, Extraversion, Agreeableness, and Neuroticism) have heritability coefficients ranging from 30% to 50%. Heritability coefficients indicate the proportion of the phenotypic variation in a population that is attributable to genetic variation among individuals. The remainder of the variance is attributable to environmental influences and measurement error. Therefore, the combination of partial heritability and partial environmentality observed in human personality variation conforms precisely to the predictions of the combination of these two theories. Where environmental cues are only partially reliable and valid, as might very often be the case, a combination of genetic diversity and developmental plasticity should become the optimal adaptive strategy.

### Behavioral Flexibility

An inability to adapt one's behavior to the different situations that one encounters in life can be considered the very definition of a personality disorder. For example, in the absence of a personality disorder, an extraverted person would still be much more likely to behave in a more introverted manner at a funeral than they would in a bar. In contrast, a personality-disordered individual would not be able to adjust his or her behavior to be situationally appropriate.

Nevertheless, personality traits are somewhat static in nature, even in normal (nondisordered) individuals. This is variously called the temporal stability and the cross-situational consistency of personality traits.

This means that, although personality differences are adaptive, an individual's behavioral flexibility may be constrained by the combination of personality traits that he or she possesses. Personality traits differ in their potential to deal effectively with particular environmental contingencies. For this reason, individuals vary in their ability to exploit the range of possibilities inherent in the situations that they might encounter.

Although some individuals might be more biologically prepared than others to behave in a particular way, they will still demonstrate some adaptive flexibility in their behavior by selecting situations that are more favorable to the expression of their genetically constrained behavioral dispositions. For example, individuals tend to gravitate toward the types of environmental situations that are most suitable for their personalities. Extraverts are more likely to be found at parties, while introverts are more likely to avoid such social situations. Thus, the cost of any constraints imposed by the possession of individual personality traits can be overcome by the benefits entailed in the selection of suitable social and ecological niches.

### Personality Disorders

These theories of the adaptive significance of traits within circumscribed social niches provide an explanation of the normal human range of variation in personality traits. Two somewhat overlapping frameworks have been offered to explain the existence of personality disorders. One view is that disorders are the result of a mismatch between inherited characteristics and current environmental conditions. The *mismatch hypothesis* suggests that the rapid rate of change in the human physical environment (e.g., from rural agricultural to high population density industrial) and social environment (e.g., from extreme social stratification represented by slavery and male superiority to more equalitarian norms) may not have allowed for a good fit between evolved personalities and current conditions, even within the lifetime of an individual. Natural selection simply has not had enough time to build up mechanisms that allow adaptation to these rapid changes occurring within historical time. However, this argument seems to be flawed in many respects. It implies that personality disorders did not exist before the rapid social change began. Furthermore, it ignores the overwhelming evidence that some personality disorders are due to biochemical imbalances.

An alternative perspective is that some variations are ill suited for particular environments. The *harmful dysfunction* hypothesis suggests that personality disorders may be due to a mismatch between organism and physical environment, or the result of sociocultural constraints that limit the effective functioning of otherwise effective mechanisms. For example, specific traits that are deemed unacceptable by society due to cultural norms or traditions may be labeled "abnormal," "disordered," or "dysfunctional" even if the traits are functioning as they were "designed" to function by natural or sexual selection. Universal standards have been shown to exist across cultures for disgust, fear, landscape preference, mate choice, and cheater detection. Hence, it is not a stretch to imagine that the same mechanisms may be at work in both the production of personality variation and in the manner in which personality traits are interpreted by others.

The psychiatric diagnosis of antisocial personality disorder (APD) can be used to illustrate these perspectives. APD is a disorder characterized by egocentric grandiosity and Machiavellianism (a tendency to deceive and manipulate others for personal gain); a smooth, glib capability to lie; shallow emotional affect; dominance; impulsivity; insensitivity to risk; goal directedness, sometimes with a lack of social emotions; and an overall lack of regard for the moral or legal standards in the local culture. The pervasive pattern of disregard for the rights of others that characterizes APD raises the question of whether this is in fact a real disorder or a group of interrelated behaviors that may be valued or devalued based on their environmental or social utility. For example, a "cheater phenotype" may increase an individual's overall reproductive success within certain ecological niches. Many "psychopaths" are known philanderers, with a history of several failed marriages and offspring by multiple partners. It is only when a mismatch between cultural constraints (e.g., norms, customs, and laws) interacts with the behaviors associated with APD that any harm or dysfunction is manifest.

The connection between the mismatch hypothesis and harmful dysfunction models of personality disorders is important in determining which physical or behavioral characteristics are truly abnormal from an evolutionary perspective. Thus, an evolutionary psychological perspective not only bridges the perceived gap between biology and culture, but it also gives a potentially workable etiology (i.e., a theory of

causation) that connects physical and behavioral disorders within a broader theoretical framework.

## PERSONALITY THEORIES, FIVE-FACTOR MODEL

---

The five-factor model of personality (FFM; often referred to as the Big Five model) is an empirically derived approach that organizes the structure of personality into five broad factors: Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness. Numerous studies have been conducted on the model and many of these lend support for the existence of the five factors across a wide

range of cultures. The five factors have been linked to numerous life outcomes, such as career and relationship trajectories, coping, health-related behaviors, well-being, and maladjustment.

### History

The origins of the FFM can be traced to William McDougall's proposal in 1932 that personality could be broadly conceptualized as being composed of five factors. Not long after, in 1934, Louis Leon Thurstone used factor analysis to reduce 60 trait adjectives down to five factors. In 1936 Gordon Allport and H. S. Odbert identified 18,000 terms in an English dictionary that could be used to describe an individual, later reducing this list to 4,000 words. Approximately 10 years later, Raymond Cattell condensed this list to 35 clusters, with 12 underlying dimensions. Cattell and his colleagues added 4 more dimensions to these 12 and developed the Sixteen Personality Factor Questionnaire (16 PF).

In the 1960s, two psychologists, Ernest C. Tupes and Raymond E. Christal, used Cattell's scales in a study of Air Force trainees. Their analysis of the data suggested the presence of five broad factors. Warren Norman replicated these five factors in 1963 and they became known as the "Norman Five."

Despite their convergence on five factors, these works remained relatively unnoticed until the late 1970s and early 1980s when several lines of independent research sparked renewed interest. Among these were studies conducted by Robert R. McCrae and Paul T. Costa, Jr., whose names have since become synonymous with the FFM or Big Five model of personality structure. Building upon the work of their predecessors, Costa and McCrae developed the NEO Personality Inventory (NEO PI) to measure the five traits. Although many different measures of the FFM have been developed, Costa and McCrae's NEO Personality Inventory-Revised (NEO PI-R) remains the most widely used and researched.

### Description and Measurement

The results of repeated independent studies have yielded interpretations consistent with the five factors named by Costa and McCrae. Neuroticism (N, sometimes referred to by its polar opposite as Emotional Stability) represents the tendency to experience psychological distress (e.g., anxiety, irritability) and to display maladaptive responses. Extraversion (E, sometimes called Surgency)

refers to a predisposition to experience positive affect (e.g., joy, passion) and to an interpersonal style that is energetic, enthusiastic, and assertive. Openness to Experience (O, sometimes called Openness to Intellect, and sometimes abbreviated as Openness) reflects a tendency to be curious and imaginative, and to seek novel experiences and ideas. Agreeableness (A, sometimes called Friendly Compliance) involves a trusting, caring, and forgiving interpersonal style. Conscientiousness (C, sometimes referred to as Dependability) pertains to an individual's level of organization, dependability, and persistence in pursuing goals.

Using measures such as the NEO PI-R, psychologists can describe an individual's personality according to these five dimensions, often referring to people as "high" or "low" on a given trait. For instance, others would most likely characterize a person who is high in Conscientiousness as dependable, reliable, hardworking, and highly motivated. Some measures of the FFM also include facet subscales that further subdivide each of the traits into more specific components.

### Multicultural Considerations

Numerous cross-cultural studies suggest that the traits described by the FFM may be universal (i.e., observed across a wide range of cultures). Using self-report and/or ratings from collaterals (e.g., friends, family, and coworkers), all five factors have been replicated in numerous linguistic and cultural contexts, including, for instance, Germany, Canada, Finland, Poland, and the former Soviet Union. However, it is important to note that, even though all five dimensions have been observed cross-culturally, the actual meaning of factors may differ across cultures. For instance, the Openness factor appears to encompass intellect as a key component when assessed in the American English, German, and Dutch languages. In the Italian language, this factor seems to convey a rebellious component.

In addition, it is possible that other traits, not included in the FFM, are important to understanding personality. For example, Interpersonal Relatedness, which involves a desire for harmony in relationships, has been observed to be important in Chinese cultures and among multiethnic individuals. Furthermore, numerically identical scores on a given scale, such as Extraversion, may actually reflect lower (or higher) levels of the trait in one culture as compared to another.

Greater within-culture variability is observed in self-reported trait scores among European as compared to Asian samples. This could be due to a tendency for Asians to avoid extreme responses, which, in turn, results in a narrower range of scores. Individual differences might also be attenuated in collectivistic cultures in which individuals sometimes de-emphasize their unique attributes to avoid "standing out" as "different." It is also possible that individual differences are simply less salient in more collectivistic cultures.

### Five-Factor Theory

McCrae and Costa have proposed a five-factor theory based on the large body of research on the FFM. The factors are included as part of a concept labeled *basic tendencies* in the theory. Rather than explaining the development of the factors themselves, the theory attempts to account for research findings on the FFM.

Basic Tendencies include personality traits and other biologically based components such as cognitive ability, perception, and sexual orientation. Although Basic Tendencies are primarily genetically based, they are also influenced by other biological mechanisms such as diseases, pharmacological interventions, and prenatal influences.

The theory also postulates Characteristic Adaptations. These result from the interaction of Basic Tendencies with External Influences (the social and physical environment, including cultural and historical context). Characteristic Adaptations include an array of psychological features, such as skills, interests, attitudes, beliefs, plans, goals, habits, self-concept, and how an individual experiences social roles and relationships. The influence of Basic Tendencies on behavior or experience is mediated by the influence of Characteristic Adaptations.

Another concept, the Objective Biography, refers to everything the individual thinks, does, or feels, and, as such, is referred to as the "output" of the personality system. The Objective Biography includes such things as one's career-related behaviors, emotional reactions, and relationship history.

Although five-factor theory is still in its infancy, it was formulated on the basis of a large body of empirical literature on the development of personality. The theory readily accounts for the stability of personality observed in numerous studies. Cross-cultural studies

also lend support to the theory. However, the theory remains to be adequately tested.

### **The Five Factors Across the Life Span**

Research indicates that personality traits, including the Big Five, tend to remain remarkably stable after age 30. Nevertheless, there is evidence of broad patterns of personality change that occur at predictable points during the life span. For instance, compared to older adults, college-age individuals tend to score higher on Neuroticism, Extraversion, and Openness, and lower on Conscientiousness and Agreeableness. These patterns of change have been observed across a wide range of cultures. Another finding that has been observed in several cultures is that women tend to score higher than men in Neuroticism, Openness, and Agreeableness.

Research on the FFM has demonstrated links between an individual's personality traits and life course. Neuroticism is the trait most clearly linked to psychological adjustment. Men who are high, versus low, in Neuroticism are more likely to develop psychological disorders. They also tend to smoke more and are more likely to demonstrate poor adjustment throughout the life span. For example, they experience greater career and marital disruption, and report lower levels of morale and life satisfaction. Men who are high on Neuroticism are also more likely to report experiencing a midlife crisis, and neuroticism in both husbands and wives is predictive of divorce.

The remaining traits appear to be associated with several positive and some negative outcomes. For instance, those high in Extraversion tend to enjoy higher income levels and greater job satisfaction, and may be more likely to emerge as leaders. Open individuals demonstrate greater evidence of creative potential and openness has been linked to higher scores on measures of intelligence, although research findings are somewhat inconsistent in this regard. High levels of openness are sometimes related to bizarre (e.g., psychotic) thinking, but open individuals may be more likely than less open individuals to seek mental health treatment when needed. Agreeable individuals often report that their goals are meaningful and they may experience more effective social relationships than those who are less agreeable. Agreeableness is often highly valued in service-related occupations. Conscientiousness is associated with increased income levels, job status, and job satisfaction. Conscientious

individuals also appear to be less likely to abuse drugs and alcohol, but extreme Conscientiousness may be linked to obsessive-compulsive features.

### **The Five-Factor Model and Coping**

Several studies have examined how personality traits relate to coping methods. Neuroticism is associated with various forms of psychopathology, such as depression, anxiety disorders, personality disorders, and somatic complaints. It appears that neurotic individuals are poor at coping, in part, because they tend to create their own distress. For instance, neurotic individuals often interpret ambiguous circumstances in more threatening ways, are more easily upset, and are prone to dramatizing minor issues. Other ineffective coping strategies associated with Neuroticism include passivity, self-blame, hostile reactions, and wishful thinking.

Conversely, Extraversion is associated with a tendency to experience positive affect, while less often experiencing negative affect. Since extraverts tend to interact more with others, it is reasonable to conclude that they are more likely (than introverts) to seek others during stressful times. Extraverts are frequently able to assess problems in a more positive light, and display more active and effective coping mechanisms.

Conscientious people are likely to use well-organized plans that aid them in coping with stress. Agreeable people may turn to social support networks to help alleviate their distress. Although Openness appears to be largely unrelated to mood and well-being, those who are more open might be expected to use their imagination to identify creative ways to cope with stressors. Overall, however, Conscientiousness and Neuroticism seem to be the best predictors of coping style.

### **The Five-Factor Model and Health Behaviors**

The FFM may be predictive of health behaviors, such as smoking, physical activity, and diet. For instance, among women, high levels of Neuroticism, Extraversion, and Openness have been linked to less healthy habits, whereas high levels of Agreeableness and Conscientiousness have been linked to healthier attitudes and behaviors. Similarly, men who are more neurotic practice fewer healthy habits, whereas those who are more conscientious and agreeable

demonstrate healthier attitudes. Conscientiousness in particular is related to longevity, which may be a function of engaging in fewer unhealthy behaviors.

Three of the five factors are linked to risky sexual behaviors. Behaviors that place one at greater risk of HIV infection (e.g., lack of condom usage) are associated with higher levels of Neuroticism and lower levels of Conscientiousness. In addition, those who are low in Openness may be prone to denying the possibility that they could become infected.

### Implications for Counseling Practice

The FFM was developed to describe normal, as opposed to pathological, personality traits. Thus, the model and its associated measures, including the NEO PI-R, appear to be well suited for an approach that emphasizes client strengths and normal, developmental concerns. The NEO PI-R, which is usually completed in 30 to 40 minutes, lends itself well to brief therapy approaches. An interpretive report is available that provides a narrative description of the client's personality and identifies potential implications regarding several clinically relevant areas (e.g., mood and psychological adjustment, coping mechanisms, interpersonal styles, cognitive processes, and motivation). In addition, collateral ratings from spouses, peers, and others may be useful, particularly within the context of marriage and family counseling.

Because measures of the FFM are not inherently focused on psychopathology, scores on the five traits can readily be discussed with clients. Such results can be useful in identifying clients' strengths and in tailoring interventions to individual clients. For instance, those who score high on Openness often engage in the spontaneous use of humor to cope with stress, whereas those low on Openness are more inclined to use faith-based coping strategies, such as prayer. Extraverted individuals might prefer group and talk-oriented therapies, whereas introverts might benefit from more directive, task-oriented approaches. Open individuals could be expected to respond well to novel, innovative approaches, whereas those lower on this trait might prefer conventional approaches that provide more structure and direction.

Counselors might also find the FFM useful in predicting clients' responses to counseling. For instance, Conscientious clients might be inclined to diligently follow treatment recommendations, and Agreeable individuals might be expected to be more cooperative

and trusting and, hence, to develop rapport quickly. In contrast, Neurotic individuals are inclined to hold unrealistic expectations, and might benefit from assistance with setting clear, realistic goals at the outset of treatment.

The FFM can also be useful in career counseling. The five broad factors are related to John Holland's six vocational interest types (i.e., Realistic, Investigative, Artistic, Social, Enterprising, and Conventional). Generally, Extraversion is associated with Enterprising and Social interests, Openness is related to Artistic and Investigative interests, and Agreeableness is associated with Social interests. However, examination of the five traits at the more specific facet level may prove most useful when assisting clients with career-related decision making. For instance, those who score high on the Ideas facet of Openness might find Investigative careers to be most satisfying, whereas those who score high on the Aesthetics facet of Openness might find Artistic careers more rewarding.

Although the NEO PI-R was not specifically designed to measure psychopathology, scores on the NEO PI-R correlate with measures of mental disorders. As such, the instrument might be useful in alerting counselors to signs of psychopathology. For instance, Neurotic individuals may be more vulnerable to developing psychological disorders. Counselors working with clients who score high on this trait might consider following up with further assessment to examine for psychopathology.

It should be noted that, although these recommendations are based on existing empirical evidence regarding the FFM, counseling process and outcome research that is specifically focused on examining the preceding predictions is needed. Additionally, it is important to attend to multicultural factors when integrating knowledge of the FFM into counseling practice. Despite extensive cross-cultural research on the FFM, it should not be assumed that the model generalizes to all cultures. Therefore, counselors would do well to consider each client's unique background when using the FFM as a framework for conceptualizing clients' presenting concerns.

## PERSONALITY THEORIES, PHENOMENOLOGICAL

---

Phenomenological approaches to personality take human experience or *subjectivity* as their primary focus. Phenomenological theorists assert that obtaining accurate knowledge of another person requires

understanding how that person experiences the world. Personal experience constitutes immediate reality. A secondary focus of phenomenological theories is *the self*. The self is thought of as a cognitive-affective structure through which experience is filtered.

### Basic Tenets

William James's famous distinction between the "I" (subject) and the "me" (object) can be used to understand all phenomenological approaches to personality. The "I" refers to experience as it occurs for an individual (e.g., what it feels like to win an award). The "me" refers to how a person thinks about her- or himself as an object of knowledge (e.g., what someone thinks about her- or himself for having won an award). In the phenomenological model, the "I" and the "me" interact to give an individual's self-consciousness its particular form.

Phenomenological theorists focus on two kinds of subjective experience. The first is how people experience themselves in relation to others. An example is how a young girl experiences herself as her parents express disapproval of her behavior. People's positive and negative experiences with others contribute to how they learn to value themselves, sometimes called *self-regard*. Carl Rogers was particularly concerned with *conditions of worth*—or expectations that others have in order for a person to be acceptable to them. If a person receives the message that certain thoughts and feelings are unacceptable to others, he or she may become uncomfortable having those experiences and distort them. When that occurs, experiences of the person's own spontaneous inclinations are not integrated into his or her self-concept and the "me" becomes less genuine or *inauthentic*. Such a constrained self is not free.

The second kind of experience is what might be called *internal monitoring*, or people's intuitive sense of their own inclinations. According to phenomenological theory, experiences that reflect a person's truer inclinations always exist in some form and can be recovered, leading to a more authentic sense of the self. Put another way, everyone has an inherent and consciously accessible potential to develop in a healthy way, and people can always learn to connect with that potential. Somewhat incorrectly, psychologists commonly consider this focus on self-actualization to be synonymous with phenomenological theory.

American phenomenological theories are also referred to as humanistic theories because they

emphasize the inherent goodness of the individual. In the work of Carl Rogers, personal experience is valued as uniquely genuine and wholesome. People may commit atrocious acts and be quite bad, but Rogers and like-minded humanists reject the notion of an inherent or inborn badness.

The strain of phenomenological theory that stresses the human capacity for self-actualization has considerable overlap with 19th-century Romanticism, which focused on the truth value of individual intuition in contrast to the rationally discovered laws of science. Like the Romantics, the proponents of a self-actualization approach are suspicious of an exclusively scientific perspective, particularly one that focuses on technical details and ignores meaning.

## Existentialism

A more European version of phenomenological theory, referred to as existentialism, also studies human experience and subjectivity, but the experiences upon which it focuses are loneliness, isolation, and death. Existential theorists believe that such ultimate concerns can be sources of a deeper personal meaning. The awareness of death in particular is considered to be uniquely human.

Existentialist theorists also point out that some people seek constraint. They choose to distort their own experience in order to narrow their world and feel safer. They regard actively choosing a constrained self as self-deception and *bad faith*.

## Strengths and Weaknesses

An important contribution of phenomenological theories is their focus on personal meaning, health, and growth. In many ways they are the immediate ancestors of what is currently called *positive psychology*. Phenomenological theorists are also psychology's original advocates of the personality trait known as Openness to Experience. A related contribution of phenomenological theories is their emphasis on the uniqueness of individual persons. This uniqueness is easily lost in the statistical methods of scientific psychology that focus on average types. The narrative tradition in modern psychology emphasizes the individualist aspect of the phenomenological model by telling stories about people. These stories are supposed to contain information that is left out of statistical summaries. Finally, the common tenet of

self-structure, where experiences congruent with that structure are accepted and experiences incongruent with that structure are rejected, has gained credence in both psychodynamic and social-cognitive theories of personality.

An important criticism of phenomenological theory highlights its tendency to suggest that individual perception and emotional intuition has some special relationship with truth. In contrast, many psychologists and philosophers cogently argue that the degree of personal conviction with which a belief is held has limited bearing on its accuracy. History offers many examples of propositions that people believed in deeply, but that turned out to be false, such as flat earth theory. Modern science with its emphasis on skepticism and experimental research has taught us to see beyond common sense and individual perception. In the scientific style of reasoning, personal experience has to be mediated by critical analysis.

Since the 17th century, the scientific outlook has contributed to the Western world's "progressive" character. Criticisms based on Romantic ideas can stand in opposition to the thinking that perpetuates this character. Rogers was quite cognizant of this problem early in his career, although in his later years he seemed to increasingly emphasize individual intuition.

## Empirical Support

Evaluating the "validity" of phenomenological theories of personality is a substantial challenge because phenomenological theory and the scientific tradition work from altogether different theories of knowledge. Phenomenological approaches are primarily interested in capturing the subjective reality of individual human beings. They propose that abstract concepts such as self-actualization, authenticity, meaning, and spirituality are essential to understanding what it means to be human. Concepts such as these are considered to be legitimate by phenomenology's standards of validity because they appear in qualitative analyses of human subjectivity. However, the ability to evaluate the validity of phenomenological constructs using quantitative empirical hypothesis testing is limited.

Despite problems in establishing the scientific validity of phenomenological postulates, empirical research does offer some support for Rogers's personality theory. According to social psychologists, individuals seek out data that verify their preexisting

self-concept, even if that self-concept is negative, as in the case of clinically depressed individuals. These behaviors highlight the importance of the self as an organizer of perceptual experiences, but they also cast doubt on the universality of seeking positive regard. Similarly, cognitive psychologists have shown that self-schemas affect how individuals process incoming information, what information they are likely to remember, and what feedback they are likely to accept about themselves. These scientifically confirmed processes offer evidence for the existence of a self-system that is quite similar to what Rogers postulated.

There is also support in clinical psychology. Marsha Linehan, an expert on borderline personality disorder (BPD), has studied the detrimental effects of *invalidating environments*. In an invalidating environment the subjectivity of a child is actively rejected and devalued. Negative emotions such as anger and sadness are especially devalued. This devaluation renders the child incapable of trusting his or her own subjective perceptions once he or she has reached adulthood. Linehan's formulation of BPD as involving intolerance of negative affect invokes claims similar to those of Rogers, such as a belief in the power of early interpersonal environments to foster healthy personality development and the value of accepting experiences as they occur.

### Implications

Phenomenological psychology's concepts such as self-actualization, authenticity, and congruence have considerable utility in the realm of personality theory and offer a persuasive depiction of human psychological life, but such concepts can become marginalized in the world of quantitative research due to their esoteric nature. Despite the widespread acceptance of the importance self-structure, phenomenological approaches are on the periphery of contemporary personality research. Even so, phenomenological methods of inquiry, such as narrative case studies, continue to provide rich, contextualized information about individual personality.

## PERSONALITY THEORIES, PSYCHODYNAMIC

---

The set of theories of personality development that are referred to collectively as psychodynamic or psychoanalytic vary dramatically in their specifics, but share a common lineage and several core concepts. Scholars agree that Sigmund Freud, the famous and controversial Austrian neurologist who wrote the first comprehensive theory of personality development, laid the foundation for all subsequent psychoanalytic theories. Similarly, the fundamental principles that tie psychodynamic theories together can be traced back to Freud's theory of psychoanalysis.

Aspects of personality development common to all psychodynamic theories are (1) the existence and importance of the unconscious and (2) the significance of childhood relationships and experiences in shaping personality. Psychodynamic theories are often further categorized according to other features they share, but there is no consensus on how various theories should be grouped. Moreover, many advocates of a psychoanalytic approach contend that, although various factions may disagree on the abstract theory that guides their understanding of personality, their therapeutic techniques or "clinical theories" are much more similar than different. Nevertheless, a common delineation of the major schools of thought is (1) Freudian, (2) ego psychology, (3) object relations theories, and (4) self psychology.

It is appropriate to add a new category to this traditional list to account for theories that have emerged in recent decades. These theories, which will be broadly referred to here as *contemporary psychodynamic theories*, are reinterpretations, integrations, and expansions

of the older theories. They are innovative in that they are informed by contemporary ideas such as systems theory, pluralism, feminism, and social constructivism.

## Freudian Theory

Freud's theory of psychoanalysis is also referred to as *classical* or *traditional psychoanalytic theory*. Certain components of Freud's comprehensive theory are sometimes also singled out and, although not technically correct, used as if they were synonymous with the whole of Freudian theory. The most common of these are *drive theory* and *structural theory*. Drive theory refers to Freud's focus on instinctual drives toward pleasure and aggression as principle motivators of human behavior. Structural theory refers to Freud's initial description of a tripartite configuration of the mind—consisting of id, ego, and superego.

Despite vehement detractors over the past century, Freud's influence has been so great that a basic understanding of his theory is necessary for any student of contemporary Western thought. It is important to remember, however, that psychoanalytic theory has evolved over time, and very few (if any) analysts today would consider themselves strict "Freudians." Instead, contemporary Freudians maintain much of Freud's theoretical foundation, but also incorporate the advances proposed by numerous followers and dissenters of Freud over the past 100 years.

Freud proposed that the human mind or psyche is primarily unconscious or out of conscious awareness. Moreover, a healthy and mature psyche is comprised of the id, ego, and superego, with the ego orchestrating an appropriate balance of id and superego activity. Freud also described developmental stages whereby infants progress from an id-dominated and superego-less state to a more balanced psyche when the superego forms at 5 or 6 years of age.

### The Id

The id is the only psychic structure that is fully present at birth. It translates the organism's needs into essential instinctual drives or wishes that are the primary motivators of behavior. The instincts that play the biggest role in Freud's theory are the drives for life and death, which are often oversimplified as sexual and aggressive drives, respectively. More precisely, however, the life instinct seeks self-preservation and species preservation; the psychic and emotional

energy associated with this drive is called *libido*. Freud theorized that a death drive, a wish for a natural dissolution to an inorganic state, must be programmed into all living things because the natural course of life is death. A primary defense against the anxiety stirred by the death instinct is aggression, which is sometimes even directed at the self (as seen in some forms of depression).

The conceptualization of the movement and power of the id's quest for wish fulfillment as a type of energy was inspired, in part, by advances in the field of thermodynamics in the 19th century. For example, Freud's description of how libidinal energy requires release is akin to how compressed physical energy is continually pushing against whatever is containing it.

Although the word *libido* became associated with sexual pleasure among the general public, Freud proposed that libidinal energy was tied to many other life-sustaining needs (e.g., eating). The part of the body that is the focus of libidinal pleasure (i.e., an erogenous zone) changes over time. In infancy, the erogenous zone is the mouth. Indeed, Freud labeled the first stage of psychosexual development the *oral stage*. He believed that proper attention to the oral needs of an infant (i.e., birth to 18 months) is necessary for healthy development. Infants who have every oral need instantly gratified are apt to be too dependent on their mothers and not resolve the psychological conflicts of this stage. Their "fixation" in the oral stage can result in dependent personality traits as adults. Infants who have their oral needs met inconsistently are liable to experience anxiety that becomes a more permanent aspect of their character. Freud also theorized that personality traits such as insatiability, cynicism, and argumentativeness had their roots in problematic experiences during the oral stage.

### The Ego

Freud proposed that the ego (or "I") begins to develop as infants use their connection with external reality to manage id drives. The ego is considered the core of the self and the part of the psyche that usually deals with external reality. Unlike the id and superego, the ego is primarily conscious. Eventually, the ego also mediates the conflict between the id and the superego, primarily through defense mechanisms such as denial, repression, and projection. Optimally, as children progress through each psychosexual stage, the ego develops more mature psychological defenses

(e.g., humor) to manage their id impulses while discharging libidinal energy. In addition, they learn other nondefensive mechanisms (e.g., frustration tolerance) to foster self-preservation. These latter functions of the ego are central in the theories that make up the branch of psychoanalysis known as *ego psychology*.

At about 18 months of age, the physical development of the toddler brings about a change in the erogenous zone. From 18 months until about 3 years of age, children are in the *anal stage*, when the anal area is the main source for the expression of libidinal energy. Freud believed that exploring and gaining control over bodily processes (e.g., toilet training) are essential for successful progression through the anal stage. Aggressive urges are often expressed as desires to gain control over others as well. Numerous potential problems that give rise to maladaptive personality traits can occur in the anal stage. For example, children who are shamed about their bodily processes may react with self-loathing or poor self-esteem. Freud also coined the term *anal retentive* to describe the overcontrolled personality type who is preoccupied with cleanliness and order. The *anal expulsive* personality, on the other hand, is crass and destructive.

### **The Superego**

From about age 3 to 5 or 6, children must navigate the *phallic stage*. For several reasons, this part of Freud's psychoanalytic theory is the most controversial. First, it ignores social taboos against thinking of children as sexual beings and suggests that incestuous feelings, albeit unconscious, are normative. In addition, many of Freud's conclusions related to this stage are considered sexist and homophobic. Third, because gender-role differences and the development of the superego are explained by events of the phallic stage, it is considered the most central to his theory and, therefore, attracts more critical attention.

Freud proposed that during the phallic stage the genitals become the primary source of sensual pleasure, although Freud differentiates this from the genital pleasure experienced by adults. Instead, pre-school-age children discover their genitals during this stage and often learn that touching themselves feels pleasurable. Freud theorized that if parents react with anger or judgment, their sons might fear that their penis would be lopped off as a punishment (which, from a boy's perspective, would also explain why his sisters lacked penises). Freud referred to this fear as

*castration anxiety* and suspected that, if not worked through, castration anxiety could cause problems with adult sexual functioning (i.e., either sexual inhibition or promiscuity).

For boys, the most important aspect of the phallic stage is the necessity to resolve what Freud referred to as the *Oedipus complex*. This developmental challenge was named for the protagonist in the ancient Greek play *Oedipus the King*, by Sophocles. As the tragic story goes, a young man who does not know he was adopted kills a man whom he later learns to be his father and marries a woman whom he later learns to be his mother. Freud proposed that normal psychosexual development leads boys to want their mother for themselves and to have hostility toward their father for frustrating this goal. Castration anxiety, however, motivates boys to displace their yearning for their mother onto other females—first girls and then women. For Freud, the Oedipal struggle ends when a boy identifies with and internalizes his father. Thus, the intrapsychic and idealized paternal authority figure is the core of the male superego.

According to Freud, the development of the superego in females is less direct and, by design, less successful, than it is in males. Freud, taking a "male as normative" perspective, theorized that castration anxiety is the best motivator of superego development; and, girls, because they do not have penises, cannot experience castration anxiety. Instead, Freud assumed that a girl in the phallic stage tends to wonder why she does not have a penis and this concern gives rise to *penis envy*. Penis envy can never be fully resolved, but indirect solutions such as marrying a man or bearing a son are possible. The first step down this path is for a girl to become more like her mother so that she can eventually attract a husband. Thus, for girls, the process of internalizing one's mother results in the formation of the superego.

The superego is a vital part of Freud's tripartite personality structure. The superego consists of two components—the *conscience* and the *ego ideal*. The former comprises the moral standards learned from parents, society, and various people or institutions that are considered moral authorities. The latter is the internalized image of one's perfect self and how one should emulate parents and other authority figures. In a sense, the conscience activates when a person is behaving in a manner contrary to his or her values, while the ego ideal activates when people reach a goal they are proud of or, alternatively, when they fail to reach a goal.

As a psychic structure that evolved to defend against Oedipal wishes, the superego can be thought of as opposite of the id. The id is concerned with fulfilling wishes and pleasing the self, while the superego is focused on denying the self and/or pleasing others. In short, the id is governed by the “pleasure principle” and the superego operates by the “morality principle.” The ego uses the “reality principle” to dissipate the resulting tension of the id–superego dichotomy.

Not surprisingly, personality problems can result from a superego that is either too weak or too strong. A weak (or nonexistent) superego results in a person who has no moral compass and may be involved in criminal activities. People with overdeveloped superegos, on the other hand, typically have personality traits such as perfectionism, overachievement, an excessive sense of responsibility, and chronic guilt about their perceived failings.

Once a child reaches age 5 or 6, he or she moves into a stage of psychosexual quiet because the libido is repressed (i.e., remains unconscious). Freud proposed that this “latency” period allows school-age children to focus on other important aspects of development such as intellectual growth, physical mastery, and social relationships. Freud did not write much about the *latency stage* or the *genital stage*, the final stage of development that begins at puberty. With regard to the formation of personality, Freud’s classical drive theory is essentially focused on events that end with the phallic stage.

A number of Freud’s followers had doubts about some aspects of traditional psychoanalytic theory. Some of the intellectuals and clinicians who were initially drawn to Freud’s innovative way of understanding human behavior followed unquestioningly, but many strove to develop or improve the theory. Some of this latter group, such as Freud’s daughter Anna, considered themselves loyal Freudians, but are now categorized differently. Other theorists, such as Carl Jung, disagreed with some of Freud’s ideas and were, in a sense, no longer welcome in Freudian circles. A third type of Freudian descendant is those psychoanalysts who actively rejected some or most of Freud’s theory and set out to develop their own. Some of these innovators developed theories that are so different from Freud’s that they are not classified under the psychoanalytic umbrella. A good example of a psychoanalyst who followed such a path is Fritz Perls, the founder of Gestalt Therapy. The remainder of this entry, however, focuses on the men and women who

extended Freud’s ideas and proposed theories of personality that have enough in common with that lineage to be considered psychoanalytic.

## Ego Psychology

In general, theorists who are considered ego psychologists focus on the motives and functions of the ego and give less attention to the drives of the id. The most prominent ego psychologists are Anna Freud, Heinz Hartmann, and Erik Erikson. Anna Freud is best known as the founder of child psychoanalysis and for the extension of her father’s notion of ego defenses. Her student, Erik Erikson, was inspired by both Sigmund and Anna Freud and developed a theory of psychosocial stages that cross the life span.

Erikson retained the structure of Freud’s first four psychosexual stages and added four adolescent and adult stages of his own. He theorized that the types of developmental challenges that individuals encounter are related to the social environment and, if not mastered, can have negative effects throughout life. For example, from about 18 months to 3 years, toddlers face the challenge of developing more autonomy from caregivers. Achieving autonomy can be facilitated by parents who allow more autonomy and do not criticize their child. If independence is thwarted, however, the child is likely to experience feelings of shame and doubt that can make it even more difficult for the child to master subsequent stages. Furthermore, the feelings of shame and doubt can affect the child’s developing personality and lead to traits such as inhibition and indecisiveness.

Hartmann viewed the development of the ego as the key to mental health. In addition to bolstering ego functions such as reality testing, judgment, and affect regulation, Hartmann argued that psychoanalysis should aim to expand analysts’ “conflict-free ego sphere.” That is, the more people are able to reason, think, and remember without emotional interference, the better they will be able to adapt to their environment.

## Object Relations Theories

According to object relations theorists, it is a drive for relationships, rather than id impulses, that shapes personality and motivates behavior. The term *object relations* refers to the largely unconscious internalized perceptions that children develop about their relationships with significant others in their life. The British theorists who are most often associated with this branch

of psychoanalytic theory are Melanie Klein, W. R. D. Fairbairn, and Donald W. Winnicott. The most notable American object relations theorists are Edith Jacobson, Margaret Mahler, and Otto F. Kernberg. Although all of these theorists are considered object relations theorists, each of their theories is unique. For example, Mahler wrote a comprehensive theory about the development of object relations from birth to age 3. She was particularly interested in the processes that allowed children to separate from their mothers and develop individuality. In addition to the internalization of how relationships are imagined by the child, Mahler's complex theory explains how children develop a stable self-concept as well as a concept of others.

Kernberg extended Mahler's ideas and wrote about a third level of internalization—the perception of the how self and other are related—which is now a central aspect of object relations theory. These templates for “self,” “other,” and “relationships” are largely responsible for how a person feels and acts in relation to him- or herself and other people. For example, the child who perceives that he or she is “good” based on his or her relationships with early caregivers will have a positive self-concept and expect to be treated well in later relationships.

Winnicott did not propose a formal theory, but he was perhaps the most influential of the early object relations theorists because he was able to present his ideas to a lay audience. It is because of Winnicott that terms such as *good enough mother*, *transitional object*, and *true self and false self* are widely known.

Another theorist who deserves mention here is John Bowlby, who developed attachment theory. Although Bowlby trained as an analyst and was strongly influenced by Anna Freud and Klein, his most innovative work emerged from his knowledge of ethology. He focused on the role of the mother–infant attachment bond in shaping a child's “internal working model” of self, other, and relationships. The ability of researchers to assess the type of attachment bond toddlers have with their caregivers has led to a tremendous amount of empirical research on attachment theory.

### Self Psychology

Heinz Kohut developed self psychology, the branch of psychoanalytic theory that took the biggest turn away from Freud's focus on the tripartite personality structure. Instead of discussing the development of and conflicts between the id, ego, and superego, Kohut focused on the interpersonal experiences that facilitate or derail the development of the “self.” The self is the core of

personality and the achievement and maintenance of a cohesive sense of self is the most important psychological function. As inherently social beings, infants and children require relationships that provide certain experiences in order to develop a healthy self. Similar *selfobject experiences* are required to maintain self-esteem over the course of life, although people can learn to provide themselves with some adequate selfobject experiences through creative endeavors, religion, and the like.

Two important selfobject functions are *mirroring* and *idealizing*, which help a person to feel known, valued, and admired, forming the core of the person's self-esteem. Kohut also wrote about the selfobject function that helps people feel interpersonally connected; he called this *twinship*.

Another key aspect of Kohut's theory is the notion that a type of narcissism or self-absorption is necessary for the normal development of a secure sense of self. Kohut labeled this particular facet of psychic structure the *grandiose self*. The other part of the *bipolar self* is the internalized parent, also referred to as the *idealized selfobject*. Over time, if parents are adequate selfobjects for the child, a healthy and cohesive self will develop. Adequate selfobjects provide a balance of mirroring (i.e., empathic approval), which supports the grandiose self, and mild empathic failures (e.g., disappointing or setting a limit with the child), which frustrates the grandiose self. Problems arise if either the grandiose self or the idealized selfobject does not develop normally. For example, without a strong idealized selfobject, people typically cannot soothe themselves when they are emotionally upset. Instead, they may turn to harmful things (e.g., alcohol) to serve this purpose.

### Contemporary Psychodynamic Theories

Theorists who have been influenced by the work of postmodern philosophers, more recent political movements, and advances in neuroscience are continuing to develop psychoanalytic theory. While the term *postmodern* means different things across disciplines and to different scholars, here it refers to a recognition that what is “real” to a person is not unitary or objective, but pluralistic and subjective. The postmodern paradigm shift means analysts and psychodynamic psychotherapy clients are no longer conceptualized as clinical specimens that can be observed and understood by an objective and neutral analyst. Instead, postmodern psychoanalysts view the therapeutic encounter as a co-construction of reality in which the subjective

experience of both parties is valid. Moreover, each person's subjective experience is necessarily embedded in the culture, context, and relationships of his or her environment and must be considered in that light. This innovative metatheory is referred to as *intersubjectivity theory*. Key figures in this movement (and the name of their theories) include Roy Shafer (action language), Irwin Z. Hoffman (dialectical constructivism), and Robert D. Stolorow (intersubjective systems theory). In addition, Jessica Benjamin and Juliet Mitchell have contributed a feminist perspective to intersubjectivity theory.

Another postmodern theorist who has made a tremendous impact on the field is Stephen A. Mitchell, who, along with Jay R. Greenberg and Lewis Aron integrated components of various theories and synthesized a postmodern relational theory of psychoanalysis. Mitchell, in particular, argued that *relational theory* should supplant classical psychoanalytic theory, which he considered obsolete. Relational theory and intersubjectivity theory are closely allied and often grouped together as postmodern psychoanalytic theories.

The newest frontier of psychoanalytic theory appears to be the presentation of research in neuroscience to validate or renovate psychoanalytic theory. Leaders in this area include psychoanalysts Glenn O. Gabbard and Drew Westen and neuroscientists Eric Kandel and Paul Grobstein.

## PERSONALITY THEORIES, SOCIAL COGNITIVE

Developed over nearly five decades by Albert Bandura, social cognitive theory—which emphasizes the reciprocal interaction of behavior, cognitive, and

other personal factors, and environmental influences on human functioning—has been carefully derived from empirical findings and subjected to repeated tests within many areas of human functioning. This reciprocal process of theory development and testing has, over the years, yielded multiple versions of this continuously evolving theoretical perspective. It is important to understand some background regarding the conceptual and empirical underpinnings of the theory before describing the theory as it stands today.

## Background

Social cognitive theory had its origins in the 1950s and 1960s with the paradigm shift from psychodynamic approaches to psychotherapy to psychotherapeutic interventions increasingly based on learning theories. In fact, Bandura was instrumental in moving psychotherapy from a predominantly intrapsychic, talk-based intervention toward more active, learning-based interventions that relied heavily on performance and mastery. A hallmark of learning approaches was the reliance on observable behavior and framing hypotheses that are open to refutation.

A landmark in this evolution toward learning-based interventions was Bandura and Richard H. Walters's seminal book *Social Learning and Personality Development*, which was published in 1963. It built upon John Dollard and Neal Miller's earlier social learning theory and argued for the importance of modeling and self-regulatory processes in behavior change. In his 1969 *Principles of Behavior Modification*, Bandura further developed this emerging *social learning theory* of human behavior. The word *social* as it is used here refers to observational learning and the attendant self-regulatory processes inherent in learning vicariously from models. Further empirical and theoretical work enhanced and expanded this social learning theory approach to behavior change throughout the 1960s and 1970s.

The range of learning theory-based therapies expanded dramatically at this time and included theorists and researchers whose work was characterized under the rubric of *behavior modification*. Although this work generally relied on Skinnerian principles and eschewed intrapsychic phenomena, Bandura's research and theoretical writings were based on broader conceptions of human functioning. Bandura's early approach to therapy encompassed Skinnerian learning by response consequences, but also emphasized learning

through observation, cognitive control, and the reciprocal determination of behavior. In Bandura's theory, the origins of personal functioning lay in the complex, ongoing, and reciprocal interaction of behavioral, environmental, and personal determinants. "Personal" influences in this model include the role of cognitive and affective variables, including self-regulatory mechanisms that enable people to guide their own behavior.

The early empirical tests of social learning theory conducted by Bandura and his colleagues focused mainly on modeling interventions with phobic disorders. Guided mastery, the treatment approach studied and refined in this line of inquiry, has proven remarkably robust and effective when applied to a broad range of phobias and anxiety disorders. It is based on the assumption that people avoid what they fear, and that avoidance can instill higher levels of anxiety about the feared object. This technique consists of systematic and repeated exposure to the feared object or situation, planned carefully such that early exposures are mild, and more intense exposures are only introduced upon extinction of anxiety associated with milder levels of exposure. This is accomplished by having the therapist, in real time, "guide" the client through the different levels of exposure, using encouragement and modeling to promote a gradual approach to the feared object or situation.

For example, people with snake phobias were exposed, at a distance, to a snake in a cage, and led through a series of steps that brought them into closer and closer contact, over time, with the caged snake, until eventually they could touch and even handle the formerly feared object. The guide in this intervention would go first at each stage, modeling approach behavior, and providing encouragement and whatever other aid was necessary. The aides and prompts were reduced and eventually eliminated as mastery increased and anxiety and fear decreased. Although clinical phobias of this type were sometimes critiqued as being far removed from the problems of real counseling clients, in fact this general procedure has been proven effective for a wide range of clinical problems, including such intransigent disorders as agoraphobia, with treatment effects often shown to generalize to areas of functioning beyond anxiety reduction.

Over the years it was established that a purely behavioral explanation of the effects of participant modeling and guided mastery was sorely inadequate. As Bandura examined the treatment components that directly produced change, he became increasingly

intrigued with the role of client beliefs about their personal competence that appeared to underlie the effectiveness of social modeling interventions. Bandura labeled these pivotal beliefs about personal competence *self-efficacy* in his landmark 1977 article “Self-Efficacy: Toward a Unifying Theory of Behavioral Change.”

### Self-Efficacy Theory

As originally proposed by Bandura, *self-efficacy expectations* refer to a person's beliefs concerning his or her ability to successfully perform a given task or behavior. Self-efficacy expectations determine whether a behavior, task, or course of action will be initiated and also influence the persistence and the amount of effort expended in pursuing a task or course of action. Efficacy precepts are therefore postulated by Bandura to be central mediators of behavior and behavior change. In this view, successful psychological interventions, regardless of their specific elements, are successful through their ability to enhance efficacy expectations. Efficacy expectations are also situation specific. Self-efficacy is not viewed as a trait, nor is it viewed as a global personality characteristic. Rather, it is a specific cognitive judgment made with regard to a specific task, behavior, choice, or course of action. Furthermore, self-efficacy often predicts future behavior better than does past performance, primarily because the effects of past behavior are mediated by cognitive judgments in the form of efficacy beliefs. A central premise running throughout Bandura's work is that people create and produce rather than simply foretell their future behavior. In other words, people are human agents, capable of directing their own behavior, and not merely hapless bystanders to environmental events or intrapsychic processes.

Efficacy expectations vary on the dimensions of level or magnitude, strength, and generality. Where behaviors can be rank ordered in terms of a hierarchy of difficulty, *level* of efficacy expectations refers to the difficulty level in that hierarchy that a person feels he or she can master. Of course, many behaviors of great import are complex and cannot be so ordered. But when tasks can be ranked in terms of the challenge presented, the level dimension of efficacy expectations is crucial. For example, the level of mathematics self-efficacy can be measured by assessing which mathematics courses a person feels confident of mastering, and can predict the point at which specific students

begin avoiding mathematics, for example, in high school when math is no longer required.

*Strength* of self-efficacy expectations refers to how confident an individual is in his or her expectations of succeeding at a given task or course of action, whatever the level. For example, whereas the level of mathematics self-efficacy might indicate the most challenging math course an individual thinks he or she can master in high school (e.g., Algebra II), strength would indicate the robustness or confidence of the individual's belief in being able to succeed at that course (e.g., on a scale ranging from no confidence to total confidence). Because individuals with high and strong efficacy expectations have confidence in their ultimate success, they are likely to initiate challenging tasks, make choices, persist in endeavors, and ultimately succeed in their chosen courses of action. A lack of confidence or weak self-efficacy regarding a behavior or behavioral domain leads an individual to avoid those behaviors for which efficacy is low and weak, undermines effort expenditure and persistence, and may also produce anxiety in relation to the behaviors for which efficacy is low and weak.

Self-efficacy strength affects not only choice, effort, and persistence but also influences thought patterns, attributions, and emotional reactions. For example, people with low and weak self-efficacy tend to doubt themselves, judge challenges to be unrealistically difficult, and tend to ascribe failure to their lack of ability. All of these thought patterns can produce debilitating negative emotions. Individuals holding high and strong efficacy beliefs, conversely, judge even difficult tasks as within their ability range, are more likely to organize their abilities well and mobilize resources necessary to ensure success, and tend to attribute success to their own efforts.

Finally, *generality* of self-efficacy expectations refers to the range of associated behaviors that are affected by the level and strength of efficacy beliefs. That is, generality indicates whether self-efficacy with regard to a particular behavior is circumscribed (limited to that specific behavior) or applies to related behaviors. For example, success on a challenging mathematics test may produce high and strong efficacy expectations for succeeding only in that course (e.g., Algebra II) or may generalize to expectations for success in other mathematics courses (e.g., pre-Calculus and Calculus) as well.

In addition to postulating this core mechanism by which behavior change occurs, Bandura also specified

four sources of information through which self-efficacy expectations are learned and by which they can be modified. These sources of information include performance accomplishments, that is, experiences of successfully performing the behaviors in question; vicarious learning or modeling (observing similar others); verbal (or social) persuasion, for example, encouragement and support from others; and physiological arousal (physical and emotional states), for example, anxiety in connection with the behavior.

Of these four sources of efficacy information, performance accomplishments are hypothesized, based on empirical observations and social learning theory, to exert the strongest influence. Mastery experiences and performance accomplishments are hypothesized to influence behavior through the strong and resilient changes they produce in efficacy beliefs. Conversely, personal failures are less likely to produce performance decrements or undermine efficacy in the face of previous successful performance accomplishments and a consequent strong self-efficacy. Modeling or vicarious learning alone is likely to exert a less potent influence on efficacy beliefs than will performance-based experiences. Decreasing debilitating anxiety and lowering other forms of negative arousal can also strengthen self-efficacy. And finally, verbal encouragement or discouragement (later referred to as *social persuasion*), although alone a weaker source of efficacy information than the other three sources, may have a strengthening or undermining effect on efficacy beliefs as well.

Because of its major role in mediating choice, performance, and persistence, self-efficacy can be useful not only in understanding and predicting behavior but also in designing interventions to change behavior. Anxiety, for example, is viewed by Bandura as a “co-effect” of self-efficacy expectations in that the level of anxiety is seen to covary inversely with the level and strength of self-efficacy expectations; as self-efficacy expectations are increased, anxiety should decrease, and vice versa. Thus, interventions focused on increasing self-efficacy expectations via attention to the sources of efficacy information should increase approach versus avoidance behavior, enhance competence, and, concurrently, decrease anxiety in relationship to the behavior.

Finally, in this first major article delineating the theoretical underpinnings of self-efficacy theory, Bandura made an important distinction between efficacy and outcome expectations. Whereas self-efficacy expectations are an individual’s cognitive judgments about his or her ability to successfully engage in a behavior or

perform a task, outcome expectations are judgments about the consequences of successfully performing the task. That is, self-efficacy beliefs address the questions, “Can I do this?” or “How confident am I that I can do this?” In contrast, outcome expectations involve the question, “What will happen if I do this?” Efficacy expectations are usually a primary influence on behavior, always important and usually primary, but outcome expectations can also be important under certain conditions. People are more likely to choose to engage in an activity not only to the extent that they view themselves as competent at performing the activity but also to the extent to that they expect their efforts to lead to valued, positive outcomes (e.g., social and self-approval, tangible rewards).

Efficacy and outcome expectations also interact with actual, or measured, ability in some predictable ways. A person with strong self-efficacy and high outcome expectations will engage in determined, confident action that is likely to be successful and personally satisfying, assuming that efficacy expectations are reasonably consistent with actual performance capabilities. Efficacy expectations that are unrealistically low compared to potential performance can be debilitating, but efficacy expectations that are somewhat high compared to available objective indicators of performance can be empowering and produce enhanced performance. This is probably often the case in individuals labeled by others as “overachievers.”

When self-efficacy is high and strong but outcome expectations are negative, self-efficacy may lead an individual to efforts at overcoming and changing aspects of the environment that fail to produce positive outcomes, in essence attempting to change his or her environment. Conversely, in the face of negative outcome expectations (or environmental unresponsiveness), an individual with low and weak self-efficacy may tend to give up easily and become despondent. An individual with both low self-efficacy and low outcome expectations is most likely to be apathetic, foregoing efforts to engage in the behavior or to change the outcomes associated with successful performance.

In addition to efficacy and outcome expectations, goals are also identified as important to the self-regulation of behavior. By setting goals, people help to organize and guide their own behavior, and to sustain it in the absence of more immediate payoffs and despite inevitable setbacks. Social cognitive theory posits that goals are importantly tied to both self-efficacy and outcome expectations: People tend to set goals that are

consistent with their views of their personal capabilities and of the outcomes they expect to attain from pursuing a particular course of action. Success or failure in reaching personal goals, in turn, provides valuable information that helps to alter or confirm self-efficacy beliefs and outcome expectations.

Although the work of Bandura and his colleagues initially focused on the role of self-efficacy expectations in the genesis and treatment of clinical syndromes such as phobias, the potential of self-efficacy theory to contribute to the understanding of, and intervention in, a variety of other clinical and counseling areas was quickly recognized. In the late 1970s and 1980s researchers began applying self-efficacy theory to a multitude of issues, such as addictive behaviors, depression, stress, health promotion, and education and instruction. In the field of counseling, Gail Hackett and Nancy Betz first extended self-efficacy theory to understanding the career development of women and the career domain more generally. Applications of self-efficacy theory were found to have considerable utility for the understanding of gender differences in academic major and occupational choice, mathematics self-efficacy, and career decisions; the performance of students in science and engineering; the educational and career behavior of racially and ethnically diverse students; and the work adjustment of adults.

### Social Cognitive Theory

With the publication in 1986 of his work *Social Foundations of Thought and Action: A Social Cognitive Theory*, Bandura formally introduced a fully developed social cognitive theory, which encompassed and extended his previous work on social learning and self-efficacy theories. In fact, *self-efficacy theory* remained the most crucial element in his theoretical model of human functioning. In his 1997 book, *Self-Efficacy: The Exercise of Control*, Bandura defined self-efficacy expectations as “beliefs in one’s capability to organize and execute the courses of action required to manage prospective situations” (p. 2). The shift in label from social *learning* to social *cognitive* theory represented not a break or radical departure from previous conceptualizations but, rather, the evolution, maturation, and considerable further refinement of many of the concepts that had been previously introduced, along with some additions and the increasing recognition of the primacy of cognitive capabilities in human functioning. Essentially, the label change reflected the fact that

Bandura’s theorizing had moved considerably beyond its earliest social learning underpinnings.

In his description of social cognitive theory in 1986, Bandura emphasized the triadic and reciprocal interaction of behavior, cognitive, and other personal factors, and environmental influences on human functioning. Furthermore, social cognitive theory rests on the recognition of the vital importance of four basic human capabilities in understanding human behavior: symbolizing capability, forethought capability, vicarious capability, and self-regulatory capability.

Symbolizing capability refers to people’s ability to form cognitive representations of their worlds, allowing them to build internal models to guide future action. Forethought is the ability to anticipate the future, including imagining the possible consequences of actions, which can provide motivation for pursuing courses of action that do not have immediate payoffs. Vicarious capabilities refer to the ability to learn from observation. People not only can learn in an imitative sense, reproducing observed behavior, but also can learn rules and expectations, and can absorb lessons from the consequences experienced by models. This can significantly reduce the amount of time necessary for learning. And finally, people learn from the direct environmental consequences of their actions and the expectations of others and self-regulate their behavior. Self-defined standards and expectations develop which then govern behavior just as effectively as do external contingencies.

Self-reflection is an integral part of the self-regulatory process, and a uniquely human capability that profoundly affects human behavior. People’s ability to analyze their own experiences, examine their thoughts and feelings, and make choices about their behavior is a crucial aspect of human functioning. And, as noted earlier, self-efficacy expectations and related self-referential thoughts are central to any understanding of human functioning. Also included under self-regulatory capabilities are self-monitoring, self-evaluation, development of internal standards such as performance goals, social referent functions such as comparisons with others, valuation of activities (e.g., interests), performance appraisals, and performance attributions.

### Applications

The research literature on the applications of social cognitive theory in counseling and clinical psychology has grown exponentially. Evidence is also accumulating for

the usefulness of social cognitive theory in intervening across domains of human functioning, including a wide range of counseling concerns.

One productive example of the applications of social cognitive theory is its extension to the area of cognitive functioning and academic performance. Studies of children's efficacy beliefs and school performance consistently demonstrate the central role of efficacy judgments in predicting academic achievement. Research on the role of the four sources of self-efficacy information has also yielded results supportive of social cognitive theory's propositions. Studies of school performance have included investigations of teacher efficacy and learner academic efficacy, that is, self-efficacy with regard to achievement in specific school subjects.

Academically oriented studies have also focused on the role of social cognitive factors in the self-regulation of learning, self-appraisal skills, coping with setbacks, persistence, effort, motivation, and task choice. Bandura himself has studied the role of the collective efficacy of teachers in student learning outcomes. More broadly, applications of social cognitive theory have guided studies of, and interventions with, physical activity and sports, healthy functioning, various medical conditions, alcohol and drug abuse, organizational performance, political efficacy, decision making, and mastery of occupational roles, to name but a few of the areas of study.

In the field of counseling psychology, there have been several notable and sustained applications of social cognitive theory. For instance, the theory has been used as a basis for studying subjective well-being (an aspect of psychological wellness), counselor development, and research productivity. The most extensive application of social cognitive theory in counseling psychology lies in the area of career development. Robert Lent, Steven Brown, and Hackett's social cognitive career theory (SCCT) builds on earlier research on self-efficacy and seeks to explain three interrelated aspects of career development: (1) how basic academic and career *interests* develop, (2) how educational and career *choices* are made, and (3) how academic and career *success* is obtained. Central variables of Bandura's social cognitive theory form the core building blocks of SCCT—self-efficacy beliefs, outcome expectations, and goals. According to SCCT, these beliefs play key roles in interest development, choice, and performance.

Career-related self-efficacy refers to an individual's personal beliefs about his or her capabilities to

perform successfully particular educational or vocational behaviors or courses of action. A person might, for instance, feel very confident in being able to accomplish tasks for successful entry into, and performance in, scientific fields, but feel much less confident about his or her abilities in social or enterprising fields, such as sales. Career-related outcome expectations refer to the expected consequences of attempting particular educational or vocational pursuits. Personal goals may be defined as a person's intentions to engage in a particular activity (e.g., to pursue a given academic major) or to attain a certain level of performance (e.g., to receive an A in a particular course).

In SCCT, interests in career-relevant activities are seen as the outgrowth of self-efficacy and outcome expectations. Interests, along with self-efficacy and outcome expectations, incline people to set and pursue particular academic and career goals. Success (or failure) in the goal pursuit process then serves as a source of performance feedback, helping to revise or stabilize self-efficacy and outcome expectations in a continuous loop. SCCT also incorporates a wide array of additional factors (e.g., abilities, culture, social supports, and barriers) that have been found to influence career development, highlighting the central paths through which individual, behavioral, and environmental factors jointly determine academic and career outcomes.

## PERSONALITY THEORIES, TRAITS

---

Traits may make up the most readily recognizable component of personality. Very simple at base, traits describe what individuals are like, often with single words such as *adventurous* or *kind*. Although traits are used commonly, both in daily life and in research, surprisingly little is known about how traits work or how they influence behavior. Instead, psychology was dominated by 70 years of skepticism that traits influence behavior, or for that matter that traits even exist. Finally, after many years of empirical investigation, psychologists now know that traits do in fact relate to consistent behavior, although this consistency is not easily discernible in behavior on any

given occasion. Furthermore, personality psychologists have discovered how traits may be organized, that traits predict a host of important life outcomes, and that traits increase in stability from adolescence through adulthood.

Traits are an important concept in counseling psychology for at least three reasons. First, the personality of clients infuses the counseling process, and traits make up a major component of personality. Second, traits are highly relevant to life success, to adjustment, and to affective and personality disorders. Third, traits constitute a useful gateway to understanding clients and to clients understanding themselves.

### What Are Traits?

There has not yet been sufficient research to determine the nature of traits or their underlying mechanisms, that is, how they work. Personality psychologists take their starting point in common sense and in the everyday ways people describe each other. From there, they diverge, and there are still multiple competing definitions of traits and theories about how they work.

### Agreement About What Traits Are

Despite these disagreements, there are at least five issues on which most trait theories agree. First, traits describe individuals and emphasize the style or manner in which individuals act, think, and feel. For example, bolder individuals act, think, and feel in a bolder manner. Second, traits are characteristics on which people differ from each other. For example, some individuals are bolder than others. Third, individuals most likely do not differ in whether or not they have the trait but rather in the degree to which they have the trait. For example, although it may be convenient to speak of bold people and timid people, it is more likely that individuals differ all along a continuous dimension of boldness.

Fourth, traits endure for at least some extended time. For example, describing someone as a bold individual is more accurate if that individual is bold for more than just a moment. Finally, traits are broad descriptions of some kind of regularity, generality, or coherence in behavior, thought, and feeling. This generality may refer to the way the individuals act across different situations, to the way they act in significant, defining situations, or to a wide range of ways they act. For example, bolder individuals engage in a variety of

bold actions, such as stating opinions, taking risks, and making decisions.

In sum, trait theories generally agree that traits describe differences between people in their styles of acting, thinking, and feeling, on continuous dimensions that show at least some enduring stability and broad generality. To call someone bold is to say that he or she behaves, thinks, and feels in bolder ways than others do, and that he or she has done so for some period of time in a variety of situations with a variety of actions.

### Three Foci of Theories About the Nature of Traits

Theories addressing the nature of traits typically focus on one of three aspects of traits. The first type of theory focuses on underlying causal forces that constitute the traits, in order to explain trait-relevant behavior. For example, Gordon W. Allport proposed one of the early and prominent theories of the causal forces underlying traits. He claimed that traits are neurocognitive structures that lead individuals to interpret a range of situations as being equivalent to each other and relevant to the trait. Although subsequent theories have proposed other causal forces, there has not been enough research yet to explain how traits cause behavior. Unresolved issues include how many causes underlie traits and the relative strengths of those causes. Also unknown is whether a given trait has the same effect in every situation, or has different effects in different situations depending on the unique features of that situation.

A second type of theory does not necessarily deny explanatory causal forces, but rather focuses attention on the behavior patterns that result from traits. For example, the density-distributions approach characterizes a person's trait by his or her entire distribution of trait-relevant behaviors, rather than by only his or her most frequent or typical way of acting. This theory finds that most individuals regularly and routinely manifest nearly all levels of most traits in their daily behavior. For example, most individuals have a normal distribution of how bold their behaviors are that ranges from very timid to very bold.

Instead of trying to explain or describe behavior, the final type of theory focuses on how the different traits relate to each other in people. One prominent such theory, the Big Five theory, concerns which traits co-occur in the same individuals to what extent. For

example, boldness and adventurousness co-occur in the same individuals but they do not co-occur frequently with calmness and security.

### Which Traits Should Be Used to Describe Individuals?

The search for traits is a search for descriptions of individuals that point out styles of acting, thinking, and feeling. These styles should be present in multiple behaviors of a given individual but present to different degrees in different individuals. It turns out that there is an overabundance of such candidates. The English language contains over 18,000 potential words for traits (e.g., the letter *a* alone provides *acerbic*, *angelic*, *active*, *adventurous*, *argumentative*, *agreeable*, *anal*, *arduous*, *ardent*, *able*, *addled*, *aloof*, *affable*, *amiable*, and many more). Adding multiword phrases, such as *can dish it out but can't take it* reveals a potentially infinite number of traits. This overabundance makes a comprehensive description of an individual seem almost impossible. Furthermore, the existence of differently named traits that might actually mean something similar (e.g., kind, charitable, gracious, and humane) creates wasted efforts. Thus, there arose a need to organize traits into a manageable structure.

Raymond B. Cattell and others applied a creative solution in the early part of the 20th century. They used the statistical technique of factor analysis to identify redundant traits, that is, those traits that usually co-occur in people. For example, if each individual has the same level of boldness as he or she has of adventurousness, then these two traits are redundant. This technique revealed the astonishing finding that eliminating redundancies reduced the number of traits from 18,000 down to only 5. For example, the traits of being bold, assertive, adventurous, talkative, dominant, and many others can be subsumed under the trait of Extraversion. The five subsuming traits, called the Big Five, are Extraversion, Agreeableness, Conscientiousness, Emotional Stability (which is also known as its opposite, Neuroticism), and Intellect. Subsequent research has shown that most other theoretically derived traits fit into the Big Five as well.

There are other significant theoretical claims about which traits are the most important. Hans J. Eysenck proposed that Psychoticism, Extraversion, and Neuroticism are the three most important traits. Jack Block proposed that Ego-Control and Ego-Resiliency

are two traits that are central to human functioning and adaptation. The interpersonal circumplex model proposed that the two traits of Dominance and Agreeableness are the most important interpersonal traits.

### Are Traits Real?

For almost 70 years, psychologists debated whether traits make much difference in people's behavior. Some argued that traits are such weak determinants of behavior relative to the immediate situation that a given individual will act very differently from occasion to occasion. Others countered that traits are such powerful determinants of behavior that each individual will act in a consistently similar way from occasion to occasion. When similarity of behavior across multiple occasions was finally assessed, it turned out that each person's behavior indeed varied a great deal from moment to moment, as much as mood varied across occasions and more than people differed from each other. For example, the typical person changed rapidly back and forth from introverted to extraverted within the course of just 2 weeks. This evidence suggested that situations are very powerful in determining momentary behavior. People's everyday intuition that traits do exist and are powerful may be based on the fact that they see the people they know in a limited range of situations. People then overgeneralize from the few instances of behavior they witness.

However, it turns out that each person has a mean or average way of acting around which he or she varies. Furthermore, measuring each person's average in successive weeks revealed these averages to be almost perfectly consistent from week to week. For example, a person's average level of Extraversion is usually the same week after week.

Thus the two positions can be integrated: Each person has his or her own different and very stable average around which he or she varies quite a bit from occasion to occasion. The stable averages reveal individuals' traits and the variability around the averages reveals their responses to situations. Interestingly, people also differ in how much they vary around their average, and this too is stable from week to week.

These findings demonstrate that individuals have enormous flexibility in how they act, think, and feel in the moment, yet still have consistent behavioral

tendencies (i.e., traits). Isolated actions do not define a person, and some people are more variable than others.

### Do Traits Matter?

While the debate raged about whether traits exist, correlational studies were quietly accumulating evidence that traits have large and diverse relationships to many of the important outcomes in life, including happiness, objective events, and even death.

Regardless of how happiness, or psychological well-being, is defined, it is strongly predicted by the Big Five traits. Happiness—defined as positive affect (e.g., excitement and enthusiasm)—is predicted more strongly by Extraversion than by any other variable, including health, money, and relationships. Happiness—defined as the absence of negative affect (e.g., little anxiety or stress)—is predicted more strongly by Emotional Stability than by any other variable. Happiness—defined as life satisfaction, the cognitive judgment of one's overall life quality—is predicted by all five traits.

Traits also predict objective outcomes. Job performance, across all levels of job complexity, is predicted by Conscientiousness. Marriage quality, conflict, abuse, and ultimately marriage dissolution, are all predicted strongly by Emotional Stability and Agreeableness. Mental health disorders have been related to all Big Five traits. Even length of life is predicted by Conscientiousness, as effectively as it is predicted by high blood pressure and high cholesterol. People higher in Conscientiousness may live as much as 5 years longer than those lower in Conscientiousness. This potentially very important finding has generated much recent research in trying to verify it and identify the causal mechanisms underlying personality's relationship to length of life.

### Can Traits Change?

Given that traits have such important life consequences, it is imperative to determine whether traits can be changed. Research has established that there is at least some genetic influence on individuals' trait levels. However, it is important not to confuse genetic influence with inability to be changed.

Researchers have accumulated extensive evidence about how traits change naturally. Longitudinal studies measure participants' traits at one age and then

years or decades later measure the same participants' traits again. These studies have converged on two general findings. First, there is evidence of slight overall mean level changes from adolescence to older adulthood. Slight decreases occur in Emotional Stability (or Neuroticism), Extraversion, and Intellect and slight increases occur in Agreeableness and Conscientiousness, Ego-Control, Delay of Gratification, and Ego-Resiliency. Second, there is substantial change in people's relative positions on personality traits during adolescence and emerging adulthood. Relative-position changes are changes when some individuals increase on the trait and others decrease, changing their positions relative to each other. For example, many adolescents become less neurotic as they grow into their 20s but some become more neurotic. As individuals grow older, however, there is increasingly less relative-position change.

These descriptive studies reveal only the natural developmental changes that occur in traits. There have been few systematic efforts to change traits, so it is unclear what would happen if a systematic effort were undertaken to, for example, change an individual's level of Emotional Stability. However, the large amount of variability in the typical individuals' trait-relevant behavior suggests that change is possible. Most individuals already routinely and regularly act at most levels of most traits, suggesting that they have at least some capacity to express traits at different levels.

### Future Directions

Several unresolved questions about traits have important implications for personality and for the quality of life. First, the nature of traits must be determined. This issue refers to the causal forces underlying traits, the patterns of behavior that are implicated by trait standing, and how traits relate to other personality components such as motives and beliefs. Second, the understanding of the organization of traits needs to be advanced. The cross-cultural generalizability of organizational schemes, their appropriateness for all individuals, and the inclusion of as yet undiscovered traits all require additional research. Third, the causal mechanisms underlying the influence of traits on life outcomes must be determined in order to provide more effective opportunities for intervention. Finally, the potential and means for change in personality

traits should be identified, given the significance of traits in life.

## PERSON–ENVIRONMENT INTERACTIONS

Plato proposed the earliest person–environment (P–E) interaction model in *The Republic* around 360 B.C. He suggested that men be assigned to jobs based on

their abilities and personality because each man is ideally suited to perform the tasks necessary for success on a single job. For example, guardians of the city must have the abilities to see the enemy quickly and pursue the enemy swiftly. This seemingly simple matching model underlies modern theories in many areas of psychology and it has led to advances in research and practice.

### The P–E Interaction Model

Although many variations of the P–E interaction model exist, all emphasize the relation between two parallel aspects of the person and environment. One aspect concerns the desires of the person and the ability of the environment to fulfill those desires. The person's desires are described by various P–E models as needs, goals, values, interests, and preferences. Although some theoretical differences exist among these constructs, in P–E interaction theory they invariably refer to the attractiveness of the environmental attributes to the person. Hereafter, they are referred to as *desires*. The properties of the environment that correspond to the desires of the person are operationalized as reinforcers, benefits, satisfiers, and payoffs; henceforth, these are termed *supplies*.

The other aspect concerns the relation of the person's abilities to the demands of the environment. The relevant abilities are referred to in P–E interaction models as aptitudes, education, experience, skills, intelligence, and *g* (i.e., general mental ability). The corresponding environmental demands are referred to as environmental climate, workload, ability requirements and task requirements. These are termed *abilities* and *demands*, respectively.

Most P–E interaction models quantify the quality of the match between the person's desires and the environmental supplies and use that information to predict some outcome. Terms for the match between individuals and environments are congruence, correspondence, and P–E fit.

P–E fit is thought to produce varied outcomes including (a) reduced stress, strain, anxiety, absenteeism, turnover intentions, and turnover; (b) improved physical health, psychological health, emotional stability, adjustment, goal-setting behavior, coping, adaptation, attitudes toward learning, and vocational choice; and (c) increased creativity, motivation, performance, occupational success, commitment, tenure, satisfaction, and morale.

Although P–E interaction models have been criticized as “static” because they emphasize relatively stable aspects of the person and environment, most depict the development of P–E fit as a dynamic process that evolves over time.

### Illustrative P–E Interaction Models

The idea that P–E fit is an important moderator of outcomes is a central theoretical construct in numerous models in vocational, counseling, educational, social, industrial/organizational, and management psychology. All P–E interaction models incorporate the structural components described above. They differ primarily in their focal desire and ability dimensions. P–E models in vocational, social, and leisure psychology illustrate the model's breadth and diversity.

#### Vocational Psychology

P–E interaction models have been used most extensively in vocational psychology. Frank Parsons's theory of vocational choice was the first application of P–E interaction theory in psychology. In 1909, he suggested that vocational choice is dependent on the abilities and temperament of the worker, the demands of the job, and the logical relations between the two. During the Great Depression, University of Minnesota psychologists Donald G. Paterson and John G. Darley directed research at the Minnesota Employment Stabilization Research Institute that firmly established the usefulness of P–E interaction models in vocational psychology. They demonstrated that matching employees to occupations using aptitude test batteries, interviews, and information about occupational ability requirements led to a more effective and stable labor force.

During the 1950s and 1960s, three students of Paterson and Darley further refined the P–E interaction model. Lloyd H. Lofquist and René V. Dawis theorized that work adjustment is a function of the fit between the individual's work personality and the work environment. According to the theory of work adjustment (TWA), optimal work adjustment occurs when the worker possesses the skills necessary for success on the job and the benefits provided by the job satisfy the psychological needs of the individual.

John L. Holland postulated the existence of six basic personality types and six corresponding work environments: Realistic, Investigative, Artistic, Social, Enterprising, and Conventional (RIASEC). Optimal

vocational adjustment occurs when individuals are employed in occupations that match their personality type. Holland proposed a hexagonal arrangement of the RIASEC personality types to make his theory easy for practitioners to understand and apply. His hexagonal congruence model has profoundly influenced occupational classification, interest measurement, and career counseling. The TWA and hexagonal congruence theory are the most thoroughly investigated and widely applied P–E interaction models ever developed.

Numerous other P–E interaction models have been proposed in vocational, industrial/organizational, and management psychology, but many of them merely reiterate some aspect of the TWA. Although these theories use different labels for their focal desires, supplies, abilities, and demands, the dynamic relations among the constructs and the predictions derived from these theories are indistinguishable from those of the TWA.

### **Social Psychology**

Social psychologists and society in general are interested in the factors that underlie attraction and love. The results of efforts to identify the critical components of interpersonal attraction suggest the operation of a P–E dynamic. The attraction a person feels for another person (i.e., the “environment” in this sense) is a function of the similarity (i.e., P–E fit) of their attitudes, values, and personality. Attraction is a function of the individual’s desire for validation of his or her attitudes, values, and personality, and the confirmation supplied by another’s adoption of similar traits. As is true in vocational adjustment and other areas of behavior, the perception of similarity is more important in predicting attraction and love than an objective measure of similarity.

The influence of similarity explains why individuals are less likely to be attracted to people from a different race or culture. However, people are more attracted to individuals from a different race or culture that share their attitudes and values than to individuals from their race and culture who have different attitudes and values. Over the years, social psychologists have investigated the romantic notion that “opposites attract” using a rich diversity of approaches, but the evidence consistently shows people are attracted to those they perceive to be similar to themselves. People are generally inclined to dislike those who differ from them in attitudes and values.

### **Leisure Psychology**

The P–E interaction model also underlies two theories of leisure behavior. Mihaly Csikszentmihalyi proposed a theory that focuses on a single skill–challenge dimension of P–E fit. He suggested that a heightened state of psychological awareness (“flow”) occurs when the skills of the individual match the challenge of the activity. Boredom occurs when the individual’s skills are greater than those needed to meet the challenge. Frustration, anxiety, or fear occurs when the individual does not possess the skills required for success in the activity.

Howard E. A. Tinsley and Diane J. Tinsley’s *theory of transcendent leisure experience* postulates that individuals differ in their psychological needs (i.e., desires) and abilities, and activities differ in the needs they satisfy (i.e., their supplies) and the abilities necessary for successful performance (i.e., their demands). Satisfaction is a function of the match (i.e., P–E fit) between the needs and abilities of the individual and the supplies of the leisure activity. Transcendent leisure experiences occur only when an optimal P–E fit is achieved.

### **Efficacy of the P–E Interaction Model**

More than 100 studies of P–E interaction models have been reported in the vocational psychology literature alone. Other relevant studies have appeared in the leisure psychology, social psychology, and educational psychology literature. The primary focus has been on the fit between the desires of the individual and the supplies of the environment. Only a few studies have examined the relation between the individual’s abilities and the environment’s demands. Satisfaction is the most frequently investigated outcome, followed by stress.

Typically, the fit of the individual to the environment is calculated by subtracting the desires of the individual from the supplies of the environment. Using this metric, a positive score indicates an oversupply, while a negative score indicates a deficit. With few exceptions, fit is positively related to criteria such as satisfaction, involvement, and trust, and negatively related to criteria such as absenteeism and turnover. The research literature supports the unequivocal conclusion that the P–E interaction model provides a valid and useful way of thinking about the interaction between individuals and their environments.

## Flaws in P–E Interaction Research

Despite this optimistic summary, numerous shortcomings are apparent in the P–E interaction research. Many of these may contribute to an understatement of the efficacy of the model. Flaws that most likely vitiate the support for the P–E interaction model include sampling inadequacies, lack of commensurate measurement, use of fit indexes, use of regression analysis, and lack of longitudinal research. The lack of cross-validation and a confirmatory bias also contribute to weaker tests of P–E models.

### *Sampling Inadequacies*

Most P–E interaction research typically samples individuals from a single or very small range of environments (i.e., occupations, college majors, or leisure activities). Furthermore, most studies focus on attributes that workers desire or outcomes that environments value. For the most part, undesirable attributes and outcomes have been ignored. These sampling anomalies restrict the range of individual desires and abilities, the range of environmental demands and supplies, and the range of P–E fit scores. The effect is to attenuate the empirical relation between P–E fit scores and outcome measures and understate the support for P–E interaction theory.

### *Lack of Commensurate Measurement*

General attitudes (e.g., attitudes toward helping) and general personality measures (e.g., altruism) do not predict specific behaviors (e.g., helping in a specific situation); accurate prediction requires greater specificity. Evaluations of P–E interaction models require commensurate measurement of the desires and abilities of the individual, the supplies and demands of the environment, and the predicted outcome. Measurement is commensurate when the same dimensions are measured for the individual, the environment, and the outcome, and the relations among these elements are examined for each specific attribute. For example, a measure of salary “fit” (actual salary level minus desired salary level) can be expected to predict satisfaction with salary, but not necessarily general satisfaction and certainly not satisfaction with coworkers or supervisors. Very little of the P–E interaction research has satisfied this critical requirement.

## *Use of Fit Indexes*

The common practice of combining information about the person and the job to produce a single overall estimate of P–E fit (i.e., a fit index) has led to the development of dozens of fit indexes. Fit indexes discard valuable information. For example, algebraic difference indexes discard information about the person’s and environment’s absolute level on the dimensions measured. Absolute and squared difference indexes further discard directional information (i.e., whether supply exceeds demand or vice versa). Furthermore, fit indexes are inherently ambiguous because they discard information about the relative contribution of each factor so the value obtained could be the result of any one of a large number of specific patterns of scores. Finally, fit indexes are less reliable than the components from which they are calculated because the unreliability of the separate components is magnified in calculating the index. Therefore, fit indexes always contain less information, are less reliable, and explain less variance in the criterion than the basic data from which they are calculated. Their widespread use results in the systematic underestimation of the efficacy of P–E interaction models.

## *Reliance on Regression Analysis*

P–E interaction research often uses regression analysis to predict criterion (i.e., outcome) scores. Hit rate analysis is preferable to regression analysis for P–E interaction research. Regression analysis treats any deviation of the predicted outcome from the actual outcome, no matter how trivial, as error, whereas hit rate analysis attempts to predict membership in broadly defined, but conceptually meaningful, groups. The meaningless discrepancies that multiple regression treats as errors can be ignored by hit rate analysis. While regression analysis considers only the magnitude of errors of prediction, hit rate analysis also allows users to consider the possibility that different types of errors may differ greatly in their social and practical consequences and in their conceptual implications for the validity of P–E interaction models. Regression analysis attempts to minimize the overall “amount” of prediction error; hit rate analysis allows scholars and practitioners to minimize the overall “cost” of prediction error.

## *Longitudinal Research*

Many P–E interaction models postulate interactions between desire-supply fit and ability-demand fit.

Furthermore, over time, persons and environments shape (i.e., influence) each other. Longitudinal research is necessary to test these possibilities. The dynamic features of P–E interaction models have been ignored so completely that we cannot even guess as to the optimal or minimally adequate follow-up intervals. This is critical because individuals quickly incorporate fortuitous consequences into the norms they use when judging future situations. For example, college students used to an annual income of \$15,000 will adjust quickly to an income of \$55,000 on their first job. Thereafter, an income of \$45,000—thrice their college income—will be seen as inadequate. Longitudinal research is necessary to test the dynamic interactions postulated by P–E interaction theories.

### Cross-Validation

Multivariate data analysis techniques such as regression analysis and hit rate analysis capitalize on sample specific quirks in the data to maximize the outcome variance explained. Cross-validating the results of multivariate analyses (i.e., applying the prediction formula to an independent sample of data) is necessary to determine whether meaningful, replicable relations exist between the predictors and criterion. Unfortunately, cross-validations of P–E interaction results are seldom reported.

### Confirmatory Bias

A confirmatory bias occurs when investigators fail to examine alternatives that would disconfirm the model under analysis. Research on the P–E interaction model provides a good example of this bias. Scholars have not compared the performance of the P–E interaction model against that of alternative models such as the present status model.

The P–E interaction model uses information about the relation between the desires of the person and the supplies of the environment, for example, to predict an outcome such as satisfaction. The more parsimonious present status model suggests that the attributes of the person are irrelevant. It attempts to predict satisfaction using only information about the environmental supplies. In short, the present status model postulates that the environment affects the satisfaction of all persons in the same way (i.e., regardless of their desires, people's satisfaction is directly related to the level of supplies the environment provides).

There is some evidence that the present status model predicts as well as the P–E interaction models under some circumstances. The circumstances under which this might occur are not clear, however, because most researchers have overlooked this possibility.

### Future Directions

The P–E interaction model provides a valid and useful way of thinking about the interactions between individuals and their environments, but further conceptual development, research using longitudinal designs, and adoption of a conceptually sound approach to data analysis are necessary to advance our understanding of the dynamic interaction between persons and environments.

## PHYSICAL ACTIVITY COUNSELING

---

Lack of regular physical activity poses a health risk, but for many people, becoming more active is a difficult goal to achieve. Physical activity counseling offers a method of helping individuals increase their physical activity levels. It adopts a person-centered approach to help individuals find ways that physical activity can be included in everyday life. Counselors must develop appropriate counseling skills as well as knowledge about physical activity. Such counseling can take place in a variety of settings, including health services, workplaces, and schools.

### Physical Inactivity as a Public Health Concern

Physical inactivity is a public health problem worldwide. Major health improvements could be achieved

if the majority of most Western populations achieved the minimum recommendations of 30 minutes of moderate activity, such as walking, on most days of the week. Strategies to promote increases in physical activity at a population level are wide ranging and include government policy, environmental changes such as increasing the number of bike paths, promotional activities led by organizations such as schools and workplaces, activities that focus on groups such as exercise classes, and individual approaches such as mailing people information or meeting with them on an individual basis to counsel about how they might achieve more physical activity in their lives.

Historically, individual approaches to increasing physical activity levels focused on sport and structured exercises that were “prescribed” to clients. Exercise prescriptions were formulated for various groups of the population such as older adults, people with type 2 diabetes, and pregnant women. However, reviews of interventions aimed at promoting physical activity have shown that a person-centered approach is likely to be more effective than a “one size fits all” prescription. In the early days of the use of the person-centered approach, a term such as *exercise consultation* or *exercise counseling* may have been used. Exercise was usually defined as a structured activity, such as attending a gym or an exercise class, with an aim of increasing fitness levels. The current preferred term is *physical activity counseling/consultation* because of the shift toward everyday activities such as walking or gardening, being considered important.

### Approaches to Physical Activity Counseling

Most approaches to physical activity counseling assume that individuals move through stages of decision making and behavior change. At one end of the spectrum, there are people who are regularly active and need encouragement to stay active; at the other end of the spectrum, there are people who have not considered being more active and who need information about the benefits an active life might bring to them. In the middle of the spectrum are individuals who are thinking about change or who may have tried to change, but have not succeeded. Sometimes moving through stages happens spontaneously or through self-help procedures. However, health professionals, such as exercise psychologists, can assist people to move through stages.

Specific guidelines about using a person-centered approach to increasing activity levels have been published. These guidelines are based on the available knowledge of what assists people in making exercise behavior change and suggest the following steps:

*Step 1: Determine physical activity history.* Discuss the reasons that the client has for wanting to increase activity. Take note of when the client was last active, the kinds of activities he or she might like now, and a measure of recent physical activity (e.g., a 7-day recall of activity).

*Step 2: Discuss decision balance.* Ask the client to consider what the pros and cons of increasing activity are for him or her. If there are more cons than pros, ask the client to consider how to minimize some of the cons.

*Step 3: Ensure social support.* Determine with the client what kind of support he or she might need and who can provide it.

*Step 4: Negotiate goals.* Help the client set realistic and time-phased goals for gradually increasing activity up to a level they have determined (e.g., “In 4 weeks’ time I would like to be walking for 30 minutes more on at least 3 days of the week”). Write these goals down.

*Step 5: Discuss relapse prevention.* If there is time or if the counseling session is with someone who is already active, then discussion on how to prevent relapse from regular activity should take place. Identifying situations in which relapses back to more sedentary living are seen to be likely, such as holidays, changing jobs, or increased family responsibilities, is a first step in preventing relapse. The client must also consider how to avoid the relapse or minimize the effect of these risky situations.

*Step 6: Provide information on local opportunities.* All information on relevant local activities, such as walking paths, swimming pools, and classes, should be on hand to supplement discussion as required.

The counseling will take 45 to 60 minutes if all six steps are dealt with in one session. Some approaches are very intensive, requiring clients to meet weekly or monthly, while other approaches have been successful with as little as two counseling sessions backed up with supporting phone calls.

Another approach to physical activity counseling comes from a general health behavior change style known as motivational interviewing. Motivational interviewing is a person-centered style that can be applied to any health-enhancing behavior, such as

trying to stop smoking, change diet, or increase physical activity. The focus of this style is to help clients think about the ambivalence they have concerning changing the behavior in question. For example, in considering the adoption of physical activity, a sedentary person may express the views that “being more active will be good for helping me lose weight,” but also believe that “physical activity is time consuming and hard work.” Counseling in the style of motivational interviewing requires the client to focus on three key issues:

1. Importance: Why should I change? Is it worthwhile?
2. Confidence: Can I change? How will I cope if . . . ?
3. Readiness: Should I do it now? What about other issues?

## Skills Required

The person doing the counseling must have excellent communication and reflective listening skills, and empathy for the people who are seeking help. Specific training in general counseling skills is a prerequisite for a physical activity counselor. Counselors must also be knowledgeable about physical activity for general and clinical populations, including any contraindications for particular groups. Finally, counselors must understand the various theories of behavior change and the various factors that will influence whether or not a person will succeed in becoming more active.

## Settings for Using Physical Activity Counseling

The primary care setting offers an opportunity to counsel people who are not achieving the minimum levels of physical activity and help them become more active.

Many clinical conditions can be improved, in terms of increased quality of life and reductions of mortality or morbidity related to the condition, by patients’ increasing their level of physical activity. Thus, outpatient and follow-up clinics for a range of conditions could provide a physical activity counseling opportunity. The strongest evidence of the benefits of increasing physical activity levels is for cardiovascular disease, type 2 diabetes, depression, certain cancers, and osteoporosis. However, there are very few clinical conditions in which increasing physical activity

would *not* be beneficial. Other locations that provide physical activity counseling opportunities include workplaces, private and public fitness and health facilities, neighborhood walking groups, slimming classes, schools, colleges, and adult education centers.

### Future Needs

There is a need to increase the evidence base on the effectiveness of physical activity counseling approaches for different segments of the population. In addition, more detailed knowledge is needed about which elements of the counseling process are linked to behavior change. Finally, the optimal duration and the frequency of counseling sessions required for long-term behavior change are not yet known.

## PHYSICAL HEALTH

---

Health concerns, even those that are not life threatening, profoundly affect people's emotional, social, sexual, and vocational functioning and cause disruptions in valued life goals and roles. Counseling psychology's core emphasis on enhancing optimal development across the life span is especially helpful when considering the interaction of disease with normal developmental processes, as well as during the long-term course of many chronic diseases and health concerns. The concept of the healthy personality, rather than the medical model of a person with disease or deficits, provides a much-needed perspective in the ongoing development of health counseling psychology. The influence of the famous 17th-century philosopher René Descartes, who believed that the mind and the body were separate entities, has been felt for centuries as Western countries have continued to bifurcate mental and physical health services. Yet it is difficult to talk about mental health issues without addressing issues of physical health. Likewise, chronic illnesses have psychological and psychosocial components. In spite of the interaction between the physical and psychological, both physical and mental health professionals often ignore the connection between these two areas.

The etiology of health problems has been conceptualized using different theoretical models, including the biomedical, psychosocial, and more recently the biopsychosocial models. Many practitioners and scholars view the biomedical model as too closely aligned with a body focus with its emphasis on disease symptoms, medication, and genetics; and the psychosocial model as too closely aligned with a mind focus with its emphasis on mood, behaviors, and relationships. In contrast, the biopsychosocial model attempts to bridge the gap between these two models by eliminating the dichotomy between mind and body that devalues the complexity of factors that contribute to health status.

### A Biopsychosocial Model of Health Status

George Engel's biopsychosocial model was the first to systematically consider the effect of psychological and

social factors in conjunction with biological factors in predicting health outcomes. Representing a radical departure from viewing health and chronic disease as due primarily to biomedical factors, this model recognized the effect of psychosocial factors such as stress, coping skills, culture, environment, and context that lead to a more complete understanding of both body and mind. More recently, Mary Ann Hoffman and Jeanine Driscoll extended this model by conceptualizing health status as ranging on a continuum from illness to wellness. Unlike Engel's model, which conceptualizes health as the presence or absence of disease or illness, this concentric model recognizes the reciprocal nature of biopsychosocial factors and views health status, or wellness, as not wholly defined as being free of disease or disability. Instead, the focus is on the quality of the individual's life because individuals may have symptomatic complaints, but may still perceive they have a high quality of life due to coping mechanisms, social support, or institutional supports.

One piece of evidence for the biopsychosocial model is the high rate of comorbidity or co-occurrence of physical and psychological conditions in clients. Physical conditions can lead to psychological outcomes or can covary with these outcomes. The corollary is true in that mental health issues can have physiological ramifications. In other words, mental health acts as both a precursor and an outcome of physical health problems. For example, it is well documented that negative emotions can intensify a range of health threats or diseases that may be influenced by the immune system—most notably, cardiovascular disease. Other research has shown that the effects of depression go beyond the negative effect on quality of life. Individuals who are chronically depressed for at least 6 years have nearly a 90% greater risk of developing cancer within the following 4 years. Eating disorders are largely viewed as a problem with psychosocial origins, but they cause significant physical ramifications. Conversely, anxiety and depression are more often found in those with chronic physical illnesses than in those without physical ailments.

Lifestyle factors such as smoking, poor dietary habits, risk taking, and lack of exercise often lead to illnesses and injuries. These illnesses can add strain to an already stressed and busy life and may lead to further illness and the onset of chronic disease. On the other hand, the presence of positive social supports may be as important as the presence of risk factors in maintaining and preventing premature death from disease. Finding positive aspects in response to a

negative or traumatic life event can serve a protective function for a person's health status. Following the diagnosis of a health problem such as cancer or HIV disease, finding benefits in refocusing on life's priorities, reconnecting with significant others, or making important lifestyle changes has been linked to increased quality of life, more positive emotions, and better health outcomes. These studies show that the mere presence of disease or illness does not necessarily lead to negative outcomes or a poor quality of life. Rather, the interplay between physical health factors and psychological factors is complex and often crucial in determining health status or outcomes.

## Counseling and Health Status

Counseling can provide insight into physical health issues by illuminating challenges, risks, strengths, and resources. The economic and the psychosocial costs of disease or poor health are enormous; illness and chronic diseases can lead to costs such as pain, loss of self-image, loss of valued roles, and changes in lifestyle. Direct costs include the tangible aspects of disease such as medical expenditures and loss of income and time. Indirect costs, those costs that are difficult to assess, include reduced productivity in work and home roles, reduced social and community interactions, strain for significant others who provide care, and strain on community resources. The interaction of physical and psychological factors is apparent from a recent national health initiative, Healthy People 2010, that identified 10 areas of major health concerns. These concerns include physical and psychological risk factors of physical activity, overweight and obesity, tobacco use, substance abuse, sexual behavior, mental health, injury and violence, environmental quality, immunization, and access to health care. Though mental health is considered a category in itself, each of the other health issues has either psychosocial contributors or consequences, which has implications for counseling.

Counselors routinely assist clients with reducing or eliminating harmful behaviors such as smoking or substance use, in identifying barriers to change, and in determining strategies to achieve more healthy lifestyles, such as using behavior modification to change eating or exercise habits. For example, increased physical activity has been shown to be beneficial for health outcomes and also can significantly reduce depressive symptoms. Psychological factors such as chronic and acute stress, negative emotions,

social support availability, ways of dealing with conflict, coping style (including playfulness), and hostility can affect health and immune functioning and resiliency. Negative emotions that arise from stress can lead to inflammatory responses that pose multiple health-related problems such as arthritis and other autoimmune disease, cardiovascular disease, and some cancers. This has been referred to as distress-related immune dysregulation and likely poses a core mechanism that underlies many health risks. Psychological interventions may be effective in alleviating distress-related immune dysregulation.

When working with individuals, it is also important to consider the multiple levels of influence on health and health behaviors. Some scholars suggest the importance of looking at micro-level variables like biology, physiology, genetics, and behavior; meso-level variables like family structure, social support, and work obligations; and macro-level variables like physical accommodations, societal factors, access to care, interventions, and social policy. This multi-layered ecological approach complements a biopsychosocial model of health and wellness.

A holistic health integration of body and mind that incorporates multiple levels of influence appears to be most beneficial when working with distressed individuals. Recognizing that health disparities are pronounced along lines of gender, race and ethnicity, income, education level, disability status, geographical location, and sexual orientation, counselors can advocate for the consideration of and attention to these cultural factors in the overall treatment of physical and mental health. In moving toward a greater integration of physical and mental health issues, counselors can help individuals utilize their psychosocial resources to buffer the effects of chronic illness and to help those who are physically well maintain their health status.

## POSITIVE PSYCHOLOGY

---

*Positive psychology* is a term that refers to efforts to organize and synthesize the psychological study of positive psychological experiences. Throughout much of its history, the field of psychology has focused on efforts to understand the nature, causes, and cures for human dysfunction. Psychologists have generated an enormous body of knowledge about human emotions, thoughts, and behaviors, such as depression, stereotyping, and violence. Martin Seligman, the psychologist most closely associated with positive psychology, dedicated a portion of his time as president of the American Psychological Association to writing about the potential for psychology to contribute to an understanding of how to help children thrive, how to create rewarding occupational experiences, how to create vital and beneficent social institutions, and how to provide every person with the opportunity to achieve a life worth living. In some sense, then, positive psychology was proposed to be a shift in perspective for the field of psychology.

Seligman and others, particularly Mihaly Csikszentmihalyi, Ed Diener, and Christopher Peterson, identified several core tenets of positive psychology. These tenets include a focus on positive traits, positive subjective experiences, and positive institutions, as well as an adherence to rigorous scientific standards for evaluating current knowledge and generating new knowledge about these areas. Positive psychology cannot be thought of as a theory or even a specialty area of

psychology like counseling, biological, cognitive, or social. It is better defined as an organizational movement that seeks to bring together and highlight commonalities among several disciplines. It is also a motivational movement, seeking to encourage increased scientific efforts and resources toward understanding and facilitating optimal human functioning.

## Historical Background

Psychology was originally a branch of philosophy. It emerged as its own discipline through early work on perception and sensation, as well as personality and psychological dysfunction. Early in the history of psychology, there were many examples of “positive psychology,” including making people’s lives more productive and meaningful, identifying and encouraging giftedness in children, and helping people find niches within the vocational world that best suited their unique talents. Following World War II, the founding of the Veterans Administration (VA; now Veterans Affairs) and National Institute of Mental Health (NIMH) led to an increasingly narrow focus on diagnosing and treating mental illness. These governmental initiatives greatly expanded the opportunities available to psychologists, and led to growth in the field. Treating psychological dysfunction and mental illness was the fundamental priority of psychologists in the VA system. Similarly, the NIMH prioritized research that sought to understand and improve treatment in these same areas. The field as a whole was heavily influenced by these postwar changes, and before long, the focus on dysfunction and pathology dominated the discipline.

Counseling psychology also emerged as a discipline in the years following World War II, and counseling psychology’s interests have historically maintained a balance between understanding the nature and treatment of psychological maladies and understanding and cultivating character strengths. Among subfields of psychology, counseling psychology has been notable for the extent to which its interest in character strengths has been supported. Several examples of this support can be found in vocational approaches, such as those of Frank Parsons and E. K. Strong, which attempted to identify people’s abilities and aspirations and match them with jobs that would be satisfying to them. Within the broader field, the humanistic movement began to influence views on human nature. The humanistic perspective highlighted people’s natural tendencies to seek personal growth and generally drew

attention to the multitude of strengths people possessed. The existentialist movement within psychology also drew attention to the human capacity to overcome adversity and create meaningful experiences from what the existential theorists regarded as the random, and often challenging, stream of life. Leading proponents of these perspectives, such as Abraham Maslow, Carl Rogers, Viktor Frankl, Rollo May, and Gordon Allport, influenced the way in which psychologists regarded the human being, and elevated the importance of the human capacity for growth and psychological strength, even during the period that was dominated by research, theory, and practice emphasizing human weaknesses and afflictions.

Donald Super introduced the term *hygiology* (the study of human psychological health) in the 1950s, and in the 1980s, Erich Fromm discussed *eudaimonia* (achieving one’s potential) and Aaron Antonovsky proposed a model of *salutogenesis* (the study of human psychological health processes). These ideas have influenced a small number of psychologists in various niches of the psychology profession, but the rapid growth and pervasive influence of positive psychology sets it apart from earlier efforts to motivate the field to understand similar positive aspects.

The last years of the 20th century in the United States were marked by one of the broadest and most prolonged periods of economic expansion in the country’s history. This period of time, between wars in the Persian Gulf region of the world, was also relatively peaceful in the United States, preceding the terrorist attacks of September 11, 2001. On a sociocultural level, Seligman introduced his ideas about positive psychology at a time in American history when a large segment of the population was experiencing notable wealth and optimism. Thus, the time might have been especially ripe for the introduction of a research agenda focusing on how average people could become great and how generally content people could flourish and become fulfilled.

Positive psychology has been quite successful in its efforts to stimulate discussion, organize disparate fields of study, and articulate a burgeoning research agenda. In a 2005 report, Seligman and colleagues noted that hundreds of articles and books have been published both in the academic and popular press since 2000. Furthermore, although the principal scientific focus has been devoted to factors associated with character strengths and living the good life, a profusion of therapeutic and quasi-therapeutic applications

has mushroomed in recent years, each promising to apply “the science of positive psychology” to various psychological and occupational dysfunctions. In contrast to the research applications of positive psychology, the therapeutic applications are still awaiting empirical scrutiny.

## Key Concepts

Many scientific pursuits fit under the positive psychology umbrella, which explains some of its broad appeal. Thus, defining what areas represent positive psychology is a challenging task. The study of character strengths and well-being are two important foci in positive psychology.

### *Character Strengths*

Among the core features of positive psychology is a focus on positive human traits. Traits are the stable characteristics of people’s thinking, feeling, motivation, and behavior that, in a sense, define who they are. One of the most ambitious projects within positive psychology is to develop a catalogue of the traits that are highly valued in nearly every culture without being constrained to any particular time period. Peterson and Seligman have called these identified traits, character strengths and virtues. A virtue is a class of traits that contains several strengths. For example, the virtue of Wisdom contains strengths that mark a person’s excellence in the area of understanding the world and life, and serving as a source of sage advice to others. Several criteria have been designated to classify traits as strengths. A partial list of the criteria for strengths includes: contributing to various fulfillments that constitute the good life; being morally valued in its own right, even in the absence of obvious beneficial outcomes; not devaluing others by its expression; having no opposite that could be desirable (e.g., the opposite of flexibility could be considered steadfastness, therefore flexibility is not a character strength); and being embodied in consensual paragons. To date, 6 virtues marked by 24 strengths have been included in the initial classification system, although psychological traits might be added or removed as research progresses.

The strengths differ greatly in terms of the amount of research attention they have received. Strengths such as spirituality and self-control have been the subject of hundreds of studies, whereas others, such as modesty or humility, have not. Some of this research

has been conducted using an instrument designed to measure the full range of strengths, the Values in Action Inventory of Strengths, designed by Peterson and colleagues. This research generally suggests that possessing character strengths is associated with happiness and being liked by others. There has been little research validating the Values in Action Inventory of Strengths, so caution is warranted in considering the findings of research that has used it. Most of the extant research has been conducted using measures of traits that predated their inclusion in the character strengths project. For example, counselors are likely to be familiar with the work on hope conducted by C. R. Snyder. Over dozens of studies, hope has emerged as an important factor in predicting happiness, distress tolerance, as well as therapy outcomes. Thus, like positive psychology itself, the study of character strengths represents a wide body of work that has existed for decades, as well as a new way of looking at, unifying, organizing, and promoting that work.

### *Well-Being Research*

An enormous body of research has demonstrated the link between the frequency and magnitude of positive emotions, like joy, love, contentment, and gratitude, and the degree to which people feel satisfied with their lives and experience physical health and life longevity. Other work has focused on how people think creatively, solve problems, succeed in group negotiations, and many other characteristics of optimal personal and social functioning. The subjective experience of positive emotions is often accompanied with observable physiological reactions, such as changes in facial expression, deactivation of the body’s stress response, and changes in the location and pattern of the brain’s activity. Because these connections are so pervasive and tantalizing, understanding how to encourage the experience of positive emotions is a central pursuit in positive psychology.

Researchers are also attempting to understand whether some types of positive emotions have different effects. For instance, biting into a chocolate cupcake is likely to give people sensory pleasure. However, if that was the first cupcake one’s child ever baked, that pleasure might be accompanied by pride. Thus, while both are positive emotions, pride in one’s child might be a more meaningful and deeper emotion than pleasure. Researchers have also demonstrated the importance to the sustained well-being of positive

emotions like curiosity, and the state known as *flow*, in which time passes unnoticed as people expand their existing skills by taking on more difficult challenges.

Beyond emotional approaches to well-being, researchers have also investigated the judgments people make about their lives as a whole. A large amount of research has focused on the factors associated with life satisfaction, or the intellectual judgment that one's life is good. Those with certain personality types (more extraverted and social) or who have developed certain kinds of relationships (close and positive) are usually more satisfied with their lives.

Researchers have also investigated the factors associated with how meaningful people feel their lives are. Lives can be experienced as meaningful for many reasons. Meaning in life refers to people's perceptions that their lives matter, that their lives are understandable, signify something, or have a purpose or mission. Research has shown that those who feel their lives are meaningful are happier, less distressed, and report less substance abuse and suicidal ideation.

## Therapeutic Applications

Michael Fordyce was the first scientist to systematically explore how to increase people's happiness, reporting a number of successful efforts in the *Journal of Counseling Psychology* in the late 1970s and early 1980s. Similar efforts have been made recently to demonstrate how various ideas central to positive psychology can be adapted to benefit human welfare and happiness. Seligman and colleagues reviewed some of the progress of their research on improving people's lives through several experiential means. According to their preliminary findings, taking time to count one's blessings, as well as making an effort to use one's signature character strengths in daily life was associated with more happiness and less depression. Other researchers have reported that expressing gratitude and committing acts of kindness were associated with happiness as well.

## Future Directions

Positive psychology is likely to move in several important directions. First, research efforts will continue to look for ways in which people's happiness can be increased. Most of this work will be done with typical, generally happy people. Second, research will increasingly focus on therapeutic applications.

Positive psychology has occasionally been criticized for focusing on happiness to the neglect of unhappiness. Research into clinical applications of positive psychology research will undoubtedly increase, probably in combination with empirically supported treatments for known presenting complaints. Third, positive psychology research will increasingly consider "the Good Life" from a multicultural and transcultural perspective. Most of psychological research, and positive psychology research, has been conducted by Western individuals on Western participants using constructs derived from Western perspectives. Diverse perspectives will undoubtedly be helpful, and indeed necessary, to understanding how to best foster human strengths and optimal functioning.

## POSITIVIST PARADIGM

Positivism emerged as a philosophical paradigm in the 19th century with Auguste Comte's rejection of metaphysics and his assertion that only scientific knowledge can reveal the truth about reality. It was later formally established as the dominant scientific method in the early part of the 20th century by members of the Vienna Circle, including Gustav Bergmann, Rudolf Carnap, Herbert Feigl, Philipp Frank, Karl Menger, Otto Neurath, and Moritz Schlick.

The Vienna Circle sought to construct a *unified scientific world-conception* that rejects the use of philosophy as a means of learning about the true nature of reality. Unfortunately, it failed as a coherent philosophy of science because of a critical inconsistency between its theory of "reality" and its theory of "knowledge."

Positivism adopted David Hume's theory of the nature of reality (i.e., philosophical ontology). Hume believed that reality consists of atomistic (micro-level) and independent events. He believed in the use of the *senses* to generate knowledge about reality (i.e., scientific method). He thought that philosophical and logical reasoning could lead us to "see" nonexistent links between events occurring simultaneously. However, positivism also adopted René Descartes's epistemology (i.e., theory of knowledge). Descartes believed that *reason* is the best way to generate knowledge about reality. His deductive method implies that events are ordered and interconnected, and therefore reality is ordered and deducible. This internal inconsistency eventually undermined the validity of positivism.

The positivist paradigm asserts that real events can be observed empirically and explained with logical analysis. The criterion for evaluating the validity of a scientific theory is whether our knowledge claims (i.e., theory-based predictions) are consistent with the information we are able to obtain using our senses. Positivist research methodology (methodological individualism) emphasizes micro-level experimentation in a lablike environment that eliminates the complexity of the external world (e.g., social, psychological, and economic linkages between unemployment, and crime or suicide). Policies are then prescribed based on conclusions derived via the "scientific method" (e.g., job training for the unemployed, antidepressants for the suicidal, and jail time for the criminal). Psychologists now realize that this yields results that have internal validity (i.e., the relations observed in the experiment are valid within

that context). While the results obtained using experimental methods provide valuable insights into the nature of reality, those results may lack external validity. That is, the relations observed in the laboratory may not be the same in the more complicated external world where a much greater number of factors interact.

A positivist dealing with complex social problems such as unemployment and crime would be concerned with their visible manifestations (i.e., the unemployed individual or criminal who can be sensed or perceived) rather than with the underlying causal mechanisms that are invisible to us. Hence, positivist prescriptions tend to treat the symptoms rather than the root cause of the problem.

Positivism exerted an important influence on scientific practice in the social sciences for decades in the early 20th century. This was especially true in the natural sciences where laboratory experiments can closely approximate the real world environment, thus allowing for accurate predictions. In the social sciences, however, human volition and uncertainty make the laboratory experiment less reliable. Ultimately, its internal inconsistency resulted in the abandonment of positivism in favor of scientific approaches such as *critical multiplism*, which is based on the belief that no one approach is ever sufficient for developing a valid understanding of a phenomenon. The application of critical judgment in investigating multiple research questions using multiple measures, samples, designs, and analyses are necessary to permit a convergence on a valid understanding of a phenomenon.

## POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) is a psychiatric disorder characterized by profound disturbances in cognitive, behavioral, and physiological functioning that occur following exposure to a psychologically traumatic event. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*, the diagnosis applies to individuals who develop a constellation of symptoms after experiencing, witnessing, or being confronted with an event involving perceived or threatened loss of life, serious injury, or loss of physical integrity and that evoked fear, helplessness, or horror (e.g., military combat, sexual or physical assault, serious accidents, and major disasters). The symptoms of PTSD are organized under three clusters: (1) reexperiencing (e.g., intrusive thoughts, nightmares, flashbacks, and psychophysiological reactivity to reminders of the trauma), (2) avoidance and emotional numbing (e.g., avoiding stimuli associated with the trauma and inability to experience a full range of emotions), and (3) hyperarousal (e.g., hypervigilance, exaggerated startle response, and sleep disruption). By definition, the symptoms must persist for more than 1 month after the trauma and produce clinically significant distress and/or impairment.

### Prevalence and Etiology of Trauma and PTSD

Epidemiological studies have found that 40% to 90% of the general population in the United States experience a traumatic event meeting the PTSD stressor criterion at some point during their lifetime. After trauma exposure, the probability of developing PTSD is estimated to be approximately 10% in the general population, although higher rates (i.e., closer to 25%) have been observed after traumatic events involving violence or life threat such as rape and military combat. Numerous factors contribute to the probability of developing the disorder, with the nature and severity of the event being the most important factor. In addition, psychosocial factors such as a family history of psychiatric illness, childhood trauma or behavior problems, and the presence of psychiatric symptoms prior to the trauma appear to mediate the relationship between trauma exposure and the subsequent development of PTSD. Individual difference factors also play a role. After controlling for trauma exposure, the rate of PTSD in women is approximately twice as

high as the rate for men. Research suggests that personality traits such as neuroticism and negative emotionality represent vulnerabilities for the development of the disorder, whereas characteristics such as hardiness function as resilience factors.

Terence M. Keane and David H. Barlow adapted Barlow's model of anxiety and panic to promote an understanding of the variables involved in the development of PTSD. This conceptual model suggests that biological and psychological vulnerabilities underlie the development of PTSD. When an individual is exposed to a traumatic life event, a true biological and psychological alarm occurs leading to both conditioning of stimuli present at the time of the event and to cognitions that incorporate anxious apprehension of a recurrence of the traumatic event. These emotionally charged stimuli then promote the development of avoidance strategies in order to effectively minimize the experience of aversive emotional reactions. The emergence of PTSD is a function of these variables as well as the strength of the social support system of the individual and his or her coping abilities in the aftermath of trauma exposure.

### Assessment of PTSD

A comprehensive clinical assessment of PTSD should include administration of structured diagnostic interviews, self-report psychometrics, and an evaluation of trauma across the life span. Several structured interviews are available and the Clinician-Administered PTSD Scale for the DSM-IV and PTSD module of the Structured Clinical Interview for the DSM-IV are standards in the field. Self-report instruments can also assist in diagnosis or provide efficient, low-cost methods for research and screening purposes. Of these, several were constructed specifically for assessing PTSD (e.g., Mississippi Scale for Combat-Related PTSD; PTSD Checklist; PTSD Diagnostic Scale) and others were derived from existing items of major inventories such as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2). Finally, instruments such as the Potential Stressful Events Interview and the Traumatic Stress Schedule can be used to evaluate trauma exposure across the life span. Virtually all of the available diagnostic measures of PTSD possess excellent psychometric properties.

### Treatment of PTSD

Treatment for PTSD typically involves the use of psychotherapy, pharmacotherapy, or both. Of the

psychotherapies, exposure-based approaches (e.g., systematic desensitization, flooding, prolonged exposure, imaginal and in vivo exposure, and implosive therapy) have received the most attention and empirical support to date. The central element of these techniques involves the gradual exposure of the client to trauma-related cues to desensitize and extinguish problematic emotional and physiological reactions. The therapeutic mechanism has been conceptualized within the framework of classical conditioning: repeated exposure to trauma-related cues (e.g., trauma-related images evoked from memory) in the absence of the feared negative consequences (e.g., the trauma itself) reduces the conditioned fear, anxiety, and avoidance characteristics of PTSD.

A second promising category of empirically validated treatments for PTSD is cognitive restructuring therapies, such as cognitive processing therapy. Based on cognitive therapy principles, this approach is designed to identify and modify dysfunctional trauma-related beliefs and to teach specific behavioral and cognitively based coping skills. The procedure may also involve tasks that include an element of exposure such as writing or describing the trauma to disclose trauma-related cognitions. Controlled studies that directly compare treatments for PTSD provide strong evidence for the efficacy of these cognitive-behavioral therapies.

Pharmacological treatment of PTSD is primarily designed to treat symptom clusters of PTSD, rather than the entire syndrome or any underlying physiological dysregulation. Several classes of antidepressants have been found to be modestly effective, including monoamine oxidase inhibitors and tricyclics, with selective serotonin reuptake inhibitors (SSRIs) having the strongest body of empirical support. The SSRIs are currently the first choice of psychopharmacological treatment for PTSD. Presently, studies are underway to examine the effectiveness of cognitive-behavioral therapies and SSRIs when administered jointly. In addition, trials examining augmentation strategies to assess the efficacy of SSRIs with atypical antipsychotic medication are also underway to determine the relative efficacy of these medications in combination.

## PROBLEM-SOLVING APPRAISAL

---

Problem-solving appraisal refers to a person's self-appraisal of his or her problem-solving abilities and attitudes (i.e., his or her self-evaluated capacity to resolve problems). Ever since John Dewey's influential 1933 publication of *How We Think*, there has been a strong focus in psychology on how people cope with their daily life problems and major life events. Much of the earliest research examined laboratory problems involving water jars and strings. More recent research has also examined how people grapple with stressful personal problems, such as relationship and career problems. Not surprisingly, applied problem solving that focuses on real-life personal problems has received a great deal of attention in counseling psychology. In 1965, John Krumboltz proclaimed that the central reason for the existence of the counseling profession was because clients needed professional assistance with problems that they were unable to resolve on their own.

More than 120 studies have been conducted on problem-solving appraisal using the Problem Solving Inventory (PSI). This entry provides a brief history of psychological research on problem solving and explains how that has led to a focus on the construct of problem-solving appraisal. Then this entry summarizes what is known about the influence of problem-solving appraisal on psychosocial adjustment, physical health, coping, and educational and career-related issues, as well as other implications.

### Historical Overview of Applied Problem Solving

The earliest applied problem-solving research focused on discreet thought processes, such as sensitivity to problems, causal thinking, and the generation of alternatives. Early models of problem solving posited a stage-sequential process, and they assumed that problem solvers would rationally progress through stages such as identifying the problem, generating alternatives, and making decisions. More recently, however, psychologists have shifted their attention to higher-order or metacognitive variables that affect how and whether a person will even attempt to solve a particular problem.

People respond to personal problems in different ways. Some people tend to attack the source of the problem. Others become very anxious and try to regulate their negative emotions associated with the stress of a problem rather than to resolve the problem itself. Some people tend to problem solve in a very systematic and persistent fashion, while others tend to make sporadic and inconsistent attempts to resolve problems. In short, some people bring a great deal of resources to resolving their problems, but others have significant problem-solving deficits. An important individual difference that influences applied problem-solving behavior is a person's problem-solving appraisal.

The PSI is the most widely used measure of problem-solving appraisal. The PSI consists of 35 items, each having 6 possible responses that vary from 1 = *strongly agree* to 6 = *strongly disagree*. The instrument provides measures of (a) Problem-Solving Confidence, defined as one's beliefs in his or her problem-solving abilities; (b) Approach-Avoidance Style, defined as one's general tendency to approach or avoid different problem-solving activities; and (c) Personal Control, defined as one's beliefs in his or her emotional and behavioral control while solving problems. An

extensive body of empirical research supports the construct, convergent, and discriminant validity of the PSI across a range of populations and cultures.

### Psychosocial Adjustment

In the past 25 years, a broad range of studies have suggested that problem-solving appraisal is associated with general psychological and social adjustment, depression, hopelessness and suicide potential, anxiety and worry, alcohol use and abuse, eating disorders, childhood adjustment, and childhood trauma. This entry focuses on the first four areas.

#### General Psychological and Social Adjustment

Individuals who have a negative (as opposed to a positive) problem-solving appraisal tend to be less well adjusted psychologically, to have more personal problems, and to experience more difficulty establishing a personal identity separate from their parents. In addition, they have fewer social skills and experience more social distress. There appears to be a dysfunctional pattern in which avoiding their problems leads to lower problem-solving confidence, and subsequently, lower psychological adjustment. The more positively individuals appraise their problem solving, the higher their levels of psychological and social adjustment.

#### Depression

A positive problem-solving appraisal is associated with lower levels of depression. Individuals' negative appraisal of their problem-solving talents is strongly predictive of depression for those experiencing high levels of stress, but not for those experiencing low levels of stress. Thus, people with a negative problem-solving appraisal are at a higher risk of depression when they are under high stress. Having a positive assessment of their problem-solving ability provides individuals with some protection against depression when they are confronted with high levels of stress.

#### Hopelessness and Suicidality

A negative problem-solving appraisal is associated with feelings of hopelessness and suicidal ideation. A person's problem-solving confidence, in particular, is a relatively strong predictor of his or her feelings of

hopelessness. Individuals with a negative (as opposed to positive) problem-solving appraisal who are under high levels of stress tend to experience higher levels of hopelessness. Thus, problem-solving appraisal is a consistent predictor of hopelessness and suicidality.

### **Anxiety and Worry**

People with a negative appraisal of their problem-solving abilities tend to experience higher levels of anxiety in general, and especially when under stress. In particular, problem-solving confidence and a sense of personal control were most strongly associated with both anxiety and worrying.

### **Physical Health**

Problem-solving appraisal is associated with a range of physical health indexes including: (a) physical health complaints and health promotion, (b) physical health complications, and (c) physical limitations.

Problem-solving appraisal is related to health expectancies, specific health complaints (e.g., chronic pain and cardiovascular problems), and health problems in general. People with a negative (as opposed to a positive) appraisal of their problem-solving skills report more health complaints, lower health expectancies, and fewer health promotion behaviors. An individual's feelings of personal control strongly relate to his or her physical health complaints. There is even some evidence that problem-solving appraisal demonstrated greater sensitivity than two standard neuropsychological problem-solving measures in (a) differentiating traumatic brain injured (TBI) patients from uninjured groups, (b) detecting treatment changes in the TBI patients' problem solving, and (c) predicting independence and integration in the community of TBI patients. In short, problem-solving appraisal is a useful predictor of self-reported health and behavioral health indicators.

### **Coping**

Problem-solving appraisal is related to cognitive and affective coping activities when dealing with stressful life problems. Specifically, there is a consistent association between a positive problem-solving appraisal and problem-focused coping (i.e., approaching and attempting to alter the cause of a stressful problem). A negative appraisal is more strongly related to

task-inhibiting and emotion-focused self-statements and a tendency to feel powerless when dealing with interpersonal problems. In addition, problem-solving confidence and the approach-avoidance style appear to be the strongest contributors to reported problem-focused coping activities. A sense of personal control was particularly related to self-reported disengaging, denial, and emotion-focused coping.

People's strategies for seeking and using helping resources are also related to their appraisal of their problem-solving skills. A positive (as opposed to negative) problem-solving appraisal is associated with more awareness of the availability of helping resources, higher rates of utilization, and more satisfaction with those resources. A more positive problem-solving appraisal also predicts more positive training experiences (e.g., problem-solving training) and better personal and career counseling outcomes. Thus, problem-solving appraisal is strongly associated with various coping activities and is predictive of associated cognitive and affective coping operations as well as outcomes of utilizing various helping resources.

### **Educational and Vocational Issues**

Individuals' appraisal of their problem-solving abilities is related to the presence of educational and vocational issues. Specifically, problem-solving appraisal is related to test anxiety, test irrelevant thinking, study skills in at-risk students, education level, and age, but not to measures of intelligence and academic aptitude. Consistent with several vocational theories (particularly maturity models), problem-solving appraisal is related to vocational identity, career decision-making variables (e.g., decision-making strategies), career planning (e.g., level of knowledge and certainty, multiple career roles for women), personality consistency, and differentiation of some types of career-undecided students. For example, people with a negative (as opposed to positive) appraisal of their problem-solving skills report lower levels of vocational identity, less certainty in their decisions about a career, less knowledge about career choices, and more dependent and intuitive decision-making strategies. More specifically, approaching problems is associated with rational decision-making and dependent decisional strategies; problem-solving confidence is related to rational and intuitive decision making; and lack of personal control is related to a need for more information for making

career decisions. Thus, problem-solving appraisal is consistently and strongly associated with both career planning and decision making.

### Implications

People's appraisal of their problem-solving ability is related to a wide range of psychological adjustment and physical health indexes, to the approach they use in coping with stressful problems, and to their resolution of educational and vocational issues. There is a robust relationship between problem-solving appraisal and measures of psychological adjustment (e.g., depression, anxiety, hopelessness, and suicidal ideation). Generally speaking, people who have a more positive appraisal of their problem-solving skills are more likely to report a positive self-concept, higher levels of self-efficacy, more social support, and lower levels of depression, anxiety, suicidal ideation, social uneasiness, and irrational beliefs. They report positive health expectancies and fewer health complaints and problems. They use problem-focused strategies to cope with stressful events and have a greater awareness, utilization, and satisfaction of coping resources. They use rational career decision-making styles, have a more well-developed vocational identity, possess greater knowledge and certainty in career planning, and experience less career indecision.

In essence, people's appraisal of their problem-solving capability is useful for understanding a broad range of human behavior, and in many (but not all) cases problem-solving appraisal appears to overlap with actual problem-solving skills. That is, based on countless problem-solving trials, people's appraisal of their problem-solving capabilities is often consistent with their actual performance in problem solving. Thus, how people evaluate their problem-solving capabilities is in general consistent with the implementation of their problem-solving skills across a range of stressful personal problems. However, there are some exceptions. For instance, some people overestimate or underestimate their problem-solving abilities for a variety of reasons, resulting in a mismatch between their problem-solving appraisal and performance. There may be complex interactions between a person's appraisal of his or her problem-solving skills and personality characteristics (e.g., sociopathic personality styles) and life situation (incarcerated adults, substance abuse). Thus, problem-solving appraisal should not be considered as synonymous with problem-solving skills.

Considerably more research has chosen to examine problem-solving appraisal, rather than other applied problem-solving inventories, in racial/ethnic minority groups in the United States and other countries (e.g., Canada, China, England, Italy, Jordan, South Africa, Taiwan, and Turkey). Nonetheless, what is known about problem-solving appraisal is based on primarily White U.S. samples. More information is needed before researchers can be sure they understand the similarities and differences in real-life problem solving across cultures.

Knowing how people appraise their problem-solving capabilities is clearly useful in understanding human psychological, physical, and vocational adjustments. In counseling, understanding how clients appraise their problem-solving capabilities can help to assess clients' strengths as well as diagnose weaknesses relative to their presenting problems, or identify students at risk. Problem-solving appraisal provides a useful perspective for promoting an understanding of clients' problem-solving style and useful information in developing successful interventions to help clients resolve troublesome problems. Given that problem-solving appraisal is learned after countless trials, it also implies that people's self-appraisal of their problem-solving skills is amenable to change. There are many promising possibilities for applied interventions to enhance problem-solving appraisal and ability to cope with stressful life events, and thereby to enhance people's life satisfaction and well-being.

## PROJECTIVE TECHNIQUES

---

Psychologists use a number of methods to assess psychopathology and personality, including structured and unstructured interviews, brief self-rated and clinician-rated measures (such as the Beck Depression Inventory), projective techniques (e.g., the Rorschach Inkblot Technique), self-report personality inventories (e.g., the Minnesota Multiphasic Personality Inventory-2; MMPI-2), behavioral assessment methods (e.g., observational techniques and diary measures), outcome and treatment monitoring measures (e.g., the Outcome Questionnaire-45), and measures completed by peers or significant others (e.g., the Peer Inventory of Personality Disorders). This entry describes research findings on the most scientifically controversial of these instruments, namely, projective techniques.

In comparison with other assessment methods, a clinician using a projective technique typically presents a client with an ambiguous stimulus (e.g., an

inkblot), or asks the client to generate a response following open-ended instructions (e.g., “Draw a person”). Thus, for projective techniques, stimuli tend to be ambiguous and the nature of response options tends to be varied. The primary logic underlying these tests is the *projective hypothesis*—in the process of making sense of an ambiguous stimulus, the respondent presumably “projects” important aspects of his or her personality onto that stimulus. The test interpreter then works “in reverse” to infer the respondent’s personality traits.

Projective techniques can be placed into five broad categories: (1) *association techniques* including inkblot tests, (2) *construction techniques* including human figure drawing tests and story creation tests such as the widely used Thematic Apperception Test (TAT), (3) *completion techniques* including sentence completion tests, (4) *arrangement or selection tests* including the Szondi Test and the Luscher Color Test, and (5) *expression techniques* such as handwriting analysis, projective doll play, and puppetry.

A common argument made for using projective techniques is that they can circumvent a client’s conscious attempts to create a specific impression on these tests, as well as the client’s unconscious defenses. Clients may not know how to answer in a healthy or sick way when presented with an ambiguous stimulus such as an inkblot, so they will not be able to purposely overreport or underreport psychopathology. Similarly, when given an open-ended task such as drawing a human figure, clients may not be able to intentionally draw a figure that suggests that they have more or less psychopathology than they really have.

If clients’ responses are shaped by their personality traits and psychopathology, then projective techniques may be able to yield valuable information about the clients. In fact, a goal of using projectives is to learn things about clients that the clients themselves do not know. Proponents of projective techniques typically claim that the test results yield important insights into their clients’ unconscious processes.

Despite the claims made for projective techniques, the percentage of clinical psychologists using projective tests declined from 72% in 1986 to 39% in 2003. The decline in the popularity of projective techniques may be partly due to criticisms that have been leveled at them, which are described below. It can also be traced to the advent of managed care, which has made psychological testing, especially testing with questionable scientific support, less financially remunerative.

The scientific research on the three most popular projective instruments: the Rorschach, the TAT, and human figure drawings are described below. This entry concludes by addressing whether projective techniques can be used to circumvent a client's defenses and evaluate unconscious motivations and conflicts.

### Rorschach

Developed by the Swiss psychiatrist Hermann Rorschach in the 1920s, the Rorschach consists of 10 inkblots that are each printed on a separate card. During the first phase of the test (the response phase), the client is handed the cards one at a time and instructed to say what each blot resembles. In general, clients are allowed to give as many or as few responses as they wish. On average, clients make about 21 responses for the 10 cards.

During the second phase (the inquiry phase), each response is reviewed as the psychologist asks questions to clarify the nature of each response. For example, the psychologist tries to determine the exact location of the perception, and whether it was affected by the color or shading of the card or by other factors. Currently, the most widely used system for administering, scoring, and interpreting the Rorschach is Exner's Comprehensive System (CS).

The controversy surrounding the Rorschach is complex and touches on a number of topics. Two of the most contentious topics are the adequacy of the normative data and evidence of the instrument's validity.

Clinicians interpret test results for individual clients by comparing their test responses with normative data, that is, with those obtained for some meaningful comparison group (e.g., the general public or a group having a specific psychiatric diagnosis). Normative data were obtained for the Rorschach by administering it to individuals in the general community. Recent evidence indicates that the Comprehensive System norms are in error.

When results for relatively normal individuals were compared with results for the CS normative samples, the relatively normal individuals deviated markedly in a direction that supposedly indicates that they have serious psychopathology. Thus, interpreting the Rorschach using the CS norms tends to make many normal individuals look emotionally disturbed. This is likely to have harmful consequences. For example, clients in psychotherapy can be persuaded that they have problems they do not really have. Similarly, in forensic settings, clients may be given the Rorschach

as part of a psychological evaluation. If they are described as having mental problems they do not really have, this could have deleterious consequences such as loss of custody of their children or denial of parole.

Validity describes whether tests measure what they are claimed to measure. There is general agreement among proponents and critics that at least some Rorschach scores are valid for their intended purposes. In particular, Rorschach scores are correlated with measurements of thought disorder, interpersonal dependency, and treatment outcome. They can also be correlated with diagnoses of mental disorders that are characterized by thought disorder such as schizophrenia. In addition, there is evidence that Rorschach scores are correlated with diagnoses of organic brain damage and measurements of hostility and anxiety.

At the same time, Rorschach advocates and Rorschach critics agree that many CS scores that clinicians interpret have not been studied adequately. These include the Coping Deficit Index, Obsessive Style Index, Hypervigilance Index, active-to-passive movement ratio, D-score, food content, anatomy and X-ray content, Intellectualization Index, and Isolation Index. In general, however, they disagree on the adequacy of the validity evidence. Critics judge a Rorschach score to have been adequately validated only if positive findings have been independently replicated, studies have been appropriately designed, and results for a test score have been consistently positive. Rorschach advocates are less explicit about the criteria they use, and at times they have defended the Rorschach on the basis of their clinical experiences.

### Thematic Apperception Test

The Thematic Apperception Test (TAT), developed by Henry Murray and his student Christiana Morgan, consists of 31 cards, with a picture of an ambiguous situation on each card. For example, one picture shows a young woman grabbing the shoulders of a young man who seems to be pulling away from her. Respondents are instructed to look at each card and construct a story describing (a) the events occurring on the card, (b) what happened before, (c) what will happen in the future, and (d) what the characters are thinking and feeling. When testing a client, clinicians typically administer between 5 and 12 of the cards. The specific cards selected for administration varies greatly across examiners.

Rules have been developed for scoring TAT protocols, but clinicians rarely use these scoring systems.

In general, validity is unimpressive when clinicians make judgments using the TAT, but better when judgments are made using formal scoring systems.

The best known scoring system for the TAT was developed by David McClelland, John Atkinson, Russell Clarke, and Edgar Lowell in 1953 to assess Henry Murray's need for achievement. The scores generated by this system correlate modestly with real-world measures of achievement. The Social Cognition and Object Relations Scale, which can be used to assess object relations (i.e., mental representations of other people), also has received empirical support. Results have been mixed for other scoring systems, including the Defense Mechanisms Manual (a TAT-based index of the defense mechanisms of denial, projection, and identification).

Although a few TAT scoring systems appear to be promising, none of the scoring systems are appropriate for clinical use because adequate norms are not available. Norms are needed so that psychologists will not (a) diagnose psychopathology when it is not really present or (b) overlook psychopathology when it is present. Without adequate TAT norms the meaning of the TAT scores is not clear.

### Human Figure Drawing Methods

Human figure drawing techniques include the Draw-A-Person, House-Tree-Person, Draw-A-Family, and Kinetic Family Drawing tests. The most frequently used version of the above drawing techniques is the Draw-A-Person test. Clients are simply instructed to draw a picture of a person, and afterward they are given a new sheet of paper and are instructed to draw a person of the opposite sex. For the House-Tree-Person test, a client may be instructed to draw a house, tree, and person all on one sheet of paper, or the client may be instructed to draw the house, tree, and person separately on three sheets of paper. For the Draw-A-Family, clients draw a picture of their whole family; for the Kinetic Family Drawing, clients are requested to draw a picture of their whole family "doing something." In each instance the drawings are interpreted for signs of psychopathology.

There are two major approaches to scoring and interpreting human figure drawings. The *sign approach* draws inferences from isolated drawing features. For example, if a human figure drawing has large eyes, a clinician might infer that the client is suspicious or paranoid. Results for the sign approach have been largely negative; the overwhelming majority of

validity coefficients have been negligible or zero. The *global approach* scores a number of features of a drawing and sums them to obtain a total score. Validity has been modest for the global approach. In particular, positive results were obtained when the Draw-A-Person: Screening Procedure for Emotional Disturbance was used to differentiate children and adolescents with conduct and oppositional disorders from normal children and adolescents.

### Use of Projective Techniques

There is ample reason for skepticism concerning most widely used projective techniques. The lack of evidence of validity and of adequate normative data are stumbling blocks for many of the routine clinical uses of the Rorschach, TAT, and human figure drawing techniques. For example, in one study, Rorschach protocols were distributed to 90 psychologists who had completed formal Rorschach training. They were instructed to assign protocols to several diagnostic categories, including "normal." Most protocols came from psychiatric patients, but some came from nonpatient adults. More than 75% of the normal adults were diagnosed as having mental disorders. For example, 12% were diagnosed as having major depression and 43% were diagnosed as having a personality disorder.

However, the results are not uniformly negative. Some Rorschach and human figure drawing scores are valid, as are some TAT scoring systems. If used cautiously, these scores can help clinicians describe some important psychological characteristics. For example, a client with a thought disorder may not be able to hide this condition on the Rorschach. Furthermore, the Washington University Sentence Completion Test (WUSCT), a measure of ego development (a construct that captures the complexity with which individuals view the world), has demonstrated impressive construct validity in a series of studies. Ironically, the WUSCT is almost never used in clinical practice, although it seems to have adequate norms and it is the most extensively validated projective technique.

There is a breach between clinical practice and scientific findings. Clinicians should not use a projective technique because it seems to work in their clinical practice. It can be difficult for clinicians to learn from clinical experience because accurate feedback is often unavailable, and also because their memories and cognitive processes are fallible. For example, clinicians who make a diagnosis typically do not receive objective feedback on the accuracy of the diagnosis. Because it

can be difficult to learn from experience, clinicians should be guided by the scientific literature when deciding how to select and interpret projective techniques.

## PSYCHOANALYSIS AND PSYCHODYNAMIC APPROACHES TO THERAPY

---

It has been over a century since Sigmund Freud first introduced psychoanalysis to the world and since

“Anna O,” one of the earliest and most famous psychoanalytic patients, described the treatment she was receiving as “the talking cure.” Since those pioneering days of psychoanalysis, the influence of this theory can be seen in the myriad theories that have come into being either as extensions of psychoanalytic ideas or as reactions to them. *Psychoanalysis* is a form of treatment in which the client typically lies on the psychoanalyst’s couch and “free associates,” while coming multiple times per week over the course of several years. *Psychodynamic psychotherapy* utilizes the constructs that inform psychoanalysis proper, but clients typically sit facing their therapists and are seen for one or two appointments per week. Treatments are often of shorter duration and some interventions may be of only a few weeks. More generally, however, psychoanalytic concepts are used in a variety of treatment contexts, including group psychotherapy, assessment, and crisis intervention. Thus, psychoanalysis has been profoundly influential in mental health interventions far beyond the classical format of the patient on the couch.

Psychoanalytic theory is simultaneously a developmental theory, a personality theory, and a theory of intervention. Freud’s original instinctual theories emphasized the role of sexuality and aggression. Since that beginning, psychoanalysis has evolved in significant new directions. Significant developments include object relations theory (which emphasizes the way in which people’s history of relationships form part of their psychology and shape them in profound ways), ego psychology (which emphasizes the complex relationship between the evolving ego and reality), separation-individuation theory (which describes the trajectory from psychological symbiosis to a sense of autonomy), self psychology (which theorizes about narcissism as a normal developmental line and about the emotional forces that create and shape people’s sense of self), and relational and interpersonal models (which emphasize the interpersonal context of the therapeutic situation and its role in resolving conflicts).

Each of these psychoanalytic theories evolved from Freud’s original framework and each emphasizes different aspects of psychological development or different ways of intervening therapeutically. Today *psychoanalysis* or *psychoanalytic treatments* refer to this collection of concepts and theoretical positions that have evolved over the past century. Within psychoanalytic theory, there are schools that favor one of these views over others, and practitioners whose work may be more informed by one of these

approaches over the others. These psychoanalytically informed therapies represent a complex set of assumptions and processes. They tend to be less directive or concretely problem solving in spirit than many other therapeutic approaches. Instead, they tend to emphasize the importance of insight and self-understanding as key curative elements in psychotherapy. Nevertheless, the different psychoanalytic schools are all derived from the core tenets of psychoanalytic theory and most psychoanalytic practitioners are conversant in all of these languages even if they emphasize one approach over the others in their own work.

### Core Assumptions

Notwithstanding this diversity of theoretical positions, psychoanalytic therapies tend to share certain core assumptions, such as the importance of the dynamic unconscious, the role of psychological defenses in mental functioning, and the importance of childhood experiences in shaping personality, including the conflicts that are the basis for psychopathology. The most central and fundamental of these shared constructs is the concept of the dynamic unconscious. One of Freud's earliest observations, the dynamic unconscious centers on the idea that there are thoughts, feelings, memories, and experiences about which people are unaware or not fully aware that form part of their psychology. Unlike some theories of unconscious perception and cognition, however, the key to the psychoanalytic use of this concept is its emphasis on psychodynamic processes. In other words, it is not only that there are memories, thoughts, and feelings that exist outside of conscious awareness, but also that these influence human motivation and behavior. Furthermore, individuals have a powerful need to keep these thoughts and feelings out of awareness because their emergence into consciousness is all too often associated with problematic feelings such as anxiety, guilt, and shame. Thus, unconscious conflicts form the basis of our motivational processes and they play a complex role in every person's life. This is true not only of specific symptomatic or pathological behaviors and patterns, but also of creative and other adaptive activities such as the choice of intimate partners, careers, and hobbies. The centrality of these unconscious processes makes them a key component to therapeutic efforts to address the problems of human living.

A closely related set of assumptions centers on the role and function of psychological defenses such as

repression, denial, projection, displacement, and identification in emotional functioning. Anna Freud posited in her classic 1936 book, *The Ego and the Mechanisms of Defense*, that defenses were involved in both normal and pathological functioning. This groundbreaking work clarified the ways in which all people use defenses adaptively as part of their engagement with the reality around them. However, when defenses become entrenched, rigid, and immutable, they lead to symptomatic and broader pathological outcomes. For example, a child may not recognize the accumulating evidence that there is no Santa Claus for a time. Use of the defense of denial allows him or her to maintain the fantasy that there are magical, all-knowing, and kind people who love and take care of us and bring special, desired gifts. In the normal course of development, reality eventually imposes itself and children give up such magical beliefs. However, a child who grows up in a home that is emotionally depriving and harsh might not be able to outgrow the use of denial as a mechanism for clinging to wished-for realities. Such a child might give up the belief in Santa Claus (because to not do so would invite ridicule from peers and others), but continue to use denial in the context of relationships. This inappropriate use of denial could make it difficult for the child to see problematic qualities in others, thereby making him or her vulnerable to destructive relationships throughout life.

A third and related perspective that is shared by psychodynamic approaches is a strong commitment to a developmental framework. Psychodynamic approaches assume that experiences across the span of development, but especially in early childhood, play a vital role in shaping personality. For this reason, psychodynamic therapists pay close attention to their clients' developmental histories. They seek to understand potentially important experiences, such as the attainment of developmental milestones, and events such as the birth of siblings, serious childhood illnesses, divorces, important family moves, the loss of important childhood attachments, and the psychological qualities and idiosyncrasies of the clients' primary childhood caretakers. It is assumed that such experiences must be explored and their imprint on the adult personality must be understood if the therapist is to help clients with their concerns. Such variables may work together in complex ways. For example, the age at which particular events take place will play a role in the child's capacity to understand and therefore on how its implications are absorbed. The same event (e.g., the death of a parent,

the divorce of one's parents, or being the victim of sexual molestation) may have a different psychological impact depending on when it transpired and whether the child's primary caregivers help the child manage the painful overwhelming experience or compound its deleterious effects.

This developmental perspective incorporates a variety of thematic interpretations as to the relevant or important issues that govern a child's development. The earliest and best known of these is Freud's formulation of the first 6 years of development as progressing from oral, to anal, to oedipal phases, at which point, Freud theorized, the key components of personality development were in place. Freud argued that specific issues and challenges govern each of these phases. The oral phase, roughly the first 18 months of life, revolves around issues of nurturance, the stability of caregivers, and dependency. The anal phase, during the next 18 months, is ostensibly about the attainment of toilet training but, more to the point, is about the struggle for autonomy and independence. The oedipal phase, between 3 and 6 years of life, is about the consolidation of gender identity and identifications with parents. Complications in one of these phases lead, through fixation, to the issues central to that phase becoming implicated in personality structure and, for some, symptomatology.

The other schools that have been noted (ego psychology, object relations, separation-individuation theory, self psychology, and the relational and interpersonal schools) each tend to examine other developmental themes in greater depth. For example, ego psychology is especially interested in people's ability to "test" reality adequately and regulate their emotions. Object relations theory examines how a person's history of interpersonal relations structures his or her sense of self and others. Separation-individuation theory focuses on the struggle between a person's wish to be dependent and his or her wish to be independent and autonomous. Self psychology looks at the evolution of a coherent sense of self and the ways in which people need and use others to organize themselves. Finally, the relational and interpersonal schools are especially attuned to how people re-create past relational patterns in current relationships, including therapeutic relationships.

Together, these models inform psychodynamic therapists about ways of understanding the issues, conflicts, and concerns that their clients bring into treatment. In effect, they provide a set of thematic guidelines that allow clinicians to understand these concerns as they

arise in the clinical setting, and they help the clinician decide whether and how to communicate these understandings to the client. Because of this relation between theory and clinical inference, a strong association exists between psychoanalytic conceptualizations and clinical process. Psychoanalysis, as a developmental and personality theory, is much more closely linked to clinical practice than are other theories.

The final core assumption of psychoanalytic theory is that childhood experiences become structured into stable, enduring psychological processes. In other words, individuals are the product of their developmental experiences. Therefore, paying close attention to a variety of clinical data in the present (e.g., symptoms, dreams, fantasies, and patterns of behavior in relationships and in other contexts) enables the clinician to discern important features of childhood experiences that may only be partly remembered (if remembered at all) and only partly understood. Thus, an important goal of psychoanalytic clinicians is to better understand aspects of their clients' past from the ways in which they operate in the present.

### Key Elements of Psychodynamic Treatment Approaches

The dynamic unconscious, the role of defenses, and the developmental perspective are central to most schools of psychoanalytic treatment. They form a conceptual framework from which a psychodynamic therapist operates in an effort to understand a client's concerns and to intervene constructively. In addition, all psychoanalytic schools of thought rely heavily on several other key concepts: free association, transference, countertransference, and the working alliance.

*Free association* refers to the "basic rule" of psychoanalysis, namely, that the client's task is to say what comes to mind during therapy sessions as opposed to having an overly structured, goal-oriented approach. The assumption is that, like a fish net, material that is unconscious is always interconnected. Inviting clients to talk about whatever occurs to them without censoring their thoughts insures that conflictual or objectionable material that comes into consciousness will be spoken.

*Transference* refers, in a narrow sense, to the ways in which the therapeutic relationship is a re-creation of important prior relationships. Psychodynamic therapists assume that, via projection, clients re-create the relationship paradigms that governed their relationships with

key attachment figures during the crucial period of childhood (especially over the first 5 or 6 years). A client who had a harsh and punitive father, for example, may come to believe that the therapist is judgmental and critical of the client. The client may misread the therapist's reactions precisely because the client developed this schema for relationships in response to the harsh attitudes that were present and pervasive in earlier relationships. This history makes these same feelings, now projected onto the therapist, feel "real" in the therapeutic situation when, in fact, the therapist is working hard to be thoughtful and nonjudgmental.

Transference can be a rich means for understanding the effects of important relationships in the client's past. As the therapist understands these past, formative relationships and conveys them to the client via interpretations, the client develops insight into how they are continuing to affect their present functioning. This allows clients to come to recognize how their experiences in their present relationships have been distorted by the influence of childhood experiences, and to change the way they relate to others.

*Countertransference* refers to the feelings that the therapist experiences within the therapeutic situation. Initially, Freud viewed countertransference feelings as obstacles to therapeutic progress that were derived from the therapists' own unresolved neurotic conflicts. These unconscious conflicts were assumed to create blind spots in the therapist, making it difficult for the therapist to listen to or to clearly understand the client's concerns. When protracted, such countertransference feelings implied that the therapists needed to be in therapy to help them understand the source of the feelings that were interfering with their therapeutic effectiveness. In fact, historically, it was considered indispensable for a psychoanalytic therapist to have been in treatment as part of his training. Didactic psychotherapy would presumably help therapists experience and understand the issues and conflicts that might interfere with their effectiveness with their clients. Psychoanalytic institutes still require their candidates to be in analysis.

By the 1960s, psychoanalytic theorists had begun having reservations about this restrictive definition of countertransference. For one thing, it was acknowledged that it is common for therapists to have feelings about their clients and about the issues that their clients discuss in treatment. Furthermore, theorists had begun to understand that therapists' feelings were often a rich source of information regarding what was occurring in

therapy. Rather than view countertransference as an impediment to the therapeutic process, psychoanalytic therapists began using their countertransference feelings as tools to help them engage with their clients more effectively, and as potential sources of information about the thoughts, feelings, and concerns which their clients were often unable to put into words.

This does not mean that all such feelings are constructive. On the contrary, it is still recognized that therapists' unconscious conflicts may interfere with their therapeutic effectiveness and may play a destructive role when these are not understood. Nevertheless, countertransference is now viewed almost universally as a vital source of material for understanding what is going on within therapy.

The *working alliance* refers to the collaborative relationship that is established in therapy between the therapist and client. The alliance must be nurtured with care throughout the process of therapy, in part because therapy does not always make the client feel good. For example, exploring past experiences that are attached to deeply painful feelings requires sensitivity and tact on the part of the therapist. Trust between the therapist and client must be established if the client is to endure the painful elements of the process. Experiences that may cause the client to feel considerable shame or guilt may be playing a vital role in the client's emotional life, but they may be the hardest things for the client to discuss in therapy precisely because of how they make the client feel. The working alliance helps the client feel safe enough to explore such difficult issues within the context of the therapeutic relationship, notwithstanding the fact that such an airing of thoughts, feelings, and experiences may temporarily make the client feel badly. It is also true, however, that for many clients there is a great deal of relief in the fact that the therapist is a warm, empathic person interested in the client's concerns. This, too, reinforces the working alliance.

The working alliance is nurtured in several ways. One is via the therapist's assuming a nonjudgmental stance toward the client's material. This stance is related to Freud's dictum that the therapist's role is that of a blank screen, or of a well-polished mirror to reflect the client's concerns. Similarly, Anna Freud described the therapist's ideal position within the therapeutic situation as equidistant from the id, the ego, and the superego. Some of these suggestions have brought the criticism that psychoanalytic therapists are too detached. However, the intent is to direct therapists toward a neutral posture vis-à-vis their clients.

This helps clients understand that their therapist is not going to respond judgmentally toward the experiences and feelings they bring into therapy.

Another way in which the working alliance is nurtured is through the creation of a stable, reliable therapeutic structure, also known as *the frame*, within which the therapy takes place. For example, psychoanalytic therapists tend to be mindful about beginning and ending sessions on time and about letting their clients know in advance about anticipated disruptions (e.g., vacations or other events) that mean that sessions will be cancelled. Generally speaking, psychoanalytic clinicians do not talk about themselves during appointments. For example, the focus remains on the client and the client's life. Similarly, most psychoanalytic therapists do not take phone calls during appointments and in other ways take pains to prevent intrusions into their sessions. These steps are understood to safeguard the therapeutic situation and they alert the client to the fact that the therapist takes the work (and the client's life) seriously. They help foster an understanding that the therapy and the therapeutic relationship exist as a stable process on which the client can rely. Strict adherence to confidentiality and to limiting therapist-client interactions to the therapy sessions also serve to create a therapy structure within which the client feels "held." In short, the frame helps foster an experience of the treatment as a safe context, and of the therapist as a reliable ally.

No review of psychoanalytically informed therapies would be complete without a discussion of *dream interpretation*. Freud considered dreams to be the royal road to the unconscious, and in the early years of psychoanalysis clinicians and their clients often devoted multiple sessions to a concerted effort to decode the meaning of a single dream. Contemporary therapists are less likely to spend as much time on a single dream as they did in Freud's day, although the meaning of a particular dream may be clarified over the course of further work. However, the view that dreams are an important source of information about the client's unconscious remains central. Freud viewed the content of dreams as standing on two legs: the present and the past. From the present a dreamer might draw from a day residue—that is, feelings, images, and situations that the dreamer has been negotiating at the moment. The dream also draws upon the past, from the organizing conflicts with which the dreamer continues to struggle.

Typically, the client is asked to free-associate (i.e., say what comes to mind spontaneously) about the

different images, themes, feelings, or situations that appear in the dream. Freud was adamant that a dream could not be understood without the dreamer's associations. He eschewed cookbook approaches to dream interpretation in which specific images might be automatically understood as linked to specific contents. The therapist attempts to make sense of the dream in relation to these associations and in relation to what the therapist has learned about the client over the course of the treatment.

Psychoanalytic notions of helpful interventions tend to revolve around two key ideas: the role of insight in therapy and the role of the therapeutic relationship as a curative agent. Insight was considered to be the lynchpin of therapeutic cure throughout the formative years of psychoanalytic theorizing. Freud's initial formulations relied on an understanding of traumatic experiences that were theorized to be unconscious (and maintained there by repression and other defenses), so gaining insight (i.e., making these unconscious memories, feelings, and anxieties conscious) was seen as a central component of the therapeutic cure. While it is often assumed that insight is an intellectualized process, Freud emphasized that an intellectual understanding, devoid of feelings and emotional engagement, was not sufficient to help clients resolve their concerns.

The role of insight in therapeutic process led psychoanalysts and psychodynamic therapists to place great importance on the role of interpretation in helping clients to resolve their emotional conflicts. *Interpretation* is a technical term for a therapist's formulation, offered to the client during the therapeutic process, of how a client is unconsciously defending against thoughts, feelings, and impulses, or of what it is that the client is defending against. In other words, an interpretation is the means by which therapists attempt to help clients better understand themselves. This perspective is seated, more broadly, in values such as the value of knowing oneself and of being honest with oneself and others. Thus, insight, and the process of better understanding the forces that have shaped one's emotional life, is a key component in the psychoanalytic process.

More recently, the importance of the therapeutic relationship itself, rather than insight alone, has become an increasingly central construct for understanding how it is that therapists help their clients resolve their concerns. Psychodynamic therapists, especially those from the relational and interpersonal schools, now give

greater weight to the working alliance. The interaction that occurs in the interpersonal field between the therapist and client can become a rich source of material for understanding how the client engages the world and a rich context within which to resolve their concerns. This is especially true if the therapeutic relationship is one in which the therapist is empathically attuned and skillful in using the relationship to understand the client's issues. Learning about healthier forms of engagement within the therapeutic relationship often translates into healthier relationships in clients' lives outside of the consulting room.

## PSYCHOEDUCATION

---

Psychoeducation combines psychotherapy with education to help participants deal with a targeted problem in their life. It has been implemented in a variety of settings, ranging from mental health clinics to

occupational training. Psychoeducation focuses on providing valuable information to clients, and helping them improve awareness, skills, and communication related to the target problem. Therapists serve as “facilitators” by setting the intervention goals and modifying the presentation of information to meet clients' needs. Psychoeducation can be used with diverse cultural and ethnic groups, and can be adapted to a number of presentation formats. Empirical evidence has shown that psychoeducation is an effective intervention that improves clients' lives by increasing knowledge, developing skills, and improving relationships.

This entry describes psychoeducation—what it is, how it differs from other modes of therapy, its basic principles and treatment components, how it is conducted, and its mechanisms of action. The entry discusses the development of psychoeducation and provides examples of the diverse settings in which this type of treatment can be used. In addition, it discusses the role of therapist as facilitator and addresses cultural concerns in psychoeducation, and concludes with a summary of the evidence supporting the use of psychoeducation.

### What Is Psychoeducation?

#### **Development of Psychoeducation**

The development of psychoeducation is related to the passage and implementation of the Community Mental Health Act of 1963, which resulted in deinstitutionalization. This act was developed to provide a more normalized way of living for individuals experiencing psychological disturbances who could be maintained on medications and treated through services in their community. Although the act was well intended, a majority of the community-based treatment was provided by overworked and understaffed community facilities. This resulted in poor or no treatment for many individuals. Deinstitutionalization failed in meeting its lofty goals and essentially abandoned those it was designed to help. This dilemma stimulated efforts to educate families on how to best care for relatives experiencing mental health difficulties. Psychoeducation was developed to fill the gap resulting from the negative effects of deinstitutionalization.

Another factor that promoted the development of psychoeducation was the shift in zeitgeist from a belief that mental illness was a result of family factors (i.e., “family blaming”) to alternative explanations of

psychopathology. This in turn led to more family-focused treatments such as psychoeducation.

### ***Definition of Psychoeducation***

Psychoeducation is a form of therapeutic intervention that combines psychotherapy and education. It can be used with individuals, families, and groups, and implemented on its own or as a supplemental treatment to other ongoing interventions (e.g., medication management and family therapy).

Psychoeducation works by increasing knowledge and improving skills. When administered in a group format, it also provides social support. Psychoeducation applies therapeutic interventions from other theoretical models (e.g., cognitive-behavioral therapy [CBT], systems approaches, client-centered therapy) and combines them with specific information relevant to the presenting concern of the client (e.g., symptoms of a particular disorder, navigating the education or mental health system, medication side effects, healthy eating or sleeping habits).

### ***Settings That Employ Psychoeducation***

Psychoeducation can be provided in a variety of settings, including hospitals, jails, the military, schools, businesses, career centers, mental health centers, and even over the Internet using chat room/discussion groups or individual contact. The treatment focus varies according to the setting and client's presenting concern. For example, psychoeducation could be used when working with the family of a child having a medical illness that affects the child's social, emotional, educational, and family functioning; when working with a husband and wife seeking marital counseling or parenting skills; or when assisting an employee to meet specific job demands.

Psychoeducation can be provided in individual, family, or group formats. Each has its distinct advantages and disadvantages. An individual format allows more time to devote to topic areas most relevant to the client, and it provides increased flexibility in covering material. A drawback is the client is not exposed to individuals with the same concerns and is therefore less likely to have an "I'm not the only one" experience. Furthermore, the client is not exposed to a social group that facilitates social learning, the development of new relations, or exposure to alternative points of view and experiences.

Family psychoeducation allows the client to address concerns affecting the family unit, and it provides increased opportunities for members to learn the same skills and assist each other with practicing and applying them. Working with the family allows members to support each other, facilitate ongoing skill practice outside of sessions, and foster consistency of the skill. A major disadvantage is the lack of opportunity to meet other families experiencing the same difficulties.

Group approaches provide opportunities for social learning, development of an additional support system, networking, and reinforcement for positive change. However, group approaches have less flexibility in scheduling, they lack the ability to focus exclusively on any one client's needs, and some clients are uneasy sharing personal information in a group setting. All of the modalities of psychoeducation discussed here are effective.

Specific types of psychoeducational groups include educational/task groups, educational/guidance groups, training/work groups, training/relations groups, and training/social skills groups. Educational/task groups emphasize a client's understanding of a particular topic (e.g., civic organizations or task forces). In contrast, educational/guidance groups help clients cope with life situations such as divorce. Training/work groups are developed by employers to provide information that will assist employees to meet work demands (e.g., supervising difficult workers). Training/relations groups focus on the development of communication and interpersonal skills. Finally, training/social skills groups work to increase social skills using education, self-exploration, didactic work, and practice. These interventions can also be provided in an individual format.

### ***Components of Psychoeducation***

Psychoeducation consists of sharing information with the client that is relevant to the specific area of concern (e.g., the presenting problem) in addition to applying the tenets of various therapeutic modalities. For instance, a therapist might use behavioral and cognitive approaches to help a client develop alternative responses to events and to address the client's cognitive distortions related to these events. The therapist would also present topic-relevant information to increase the client's understanding of cognitive distortions, and use skill-building techniques (e.g., communication and problem-solving skills) to increase the client's ability to successfully apply the information.

## ***Format and Duration***

In individual or family psychotherapy, the therapist and client develop client-specific activities. Psychoeducation uses a “fixed but flexible” model. Treatment begins by focusing on a specific topic (e.g., improving a family and child’s management of mood disorders or improving an employee’s success in a job situation). Session content is prearranged; the “course outline” is typically shared with the client at the first session. However, new topics the client presents can be integrated into the prepared session content.

Session content can be presented verbally through discussion, presentation, and/or demonstration; through role playing; by video; or by invited guest presenters or lecturers. Information is typically provided in more than one medium. For example, if the therapist verbally describes and processes information with the client, written materials that elaborate on or summarize the topics and information might also be provided. This provides exposure via a variety of modalities, enhancing the likelihood the client will integrate and recall the information. Practicing new techniques via role-plays allows the therapist to process with the client any foreseen obstacles to completing the between-session project. Reviewing the project at the next session is paramount.

Session length and treatment duration typically are established at treatment onset. For example, a college student wishing to improve study skills might attend one 2-hour session. In contrast, an employee might attend five 1-hour sessions on managing stress in the workplace. Some psychoeducational treatments allow one or more “flex” sessions to be used as needed to address specific concerns of the client.

## ***Group Settings***

Psychoeducation can be provided in individual or group settings with minor adjustment to the materials. Most important, materials must be developmentally appropriate, topics must be relevant, and session length must be sufficient for the number of participants. Basic information can be presented simultaneously to individuals who differ in their understanding and experience of the topic. This approach mimics Lev Vygotsky’s zone of proximal development, whereby the client’s ability to use the information presented is facilitated by the client’s prior experiences and problem-solving skills, under appropriate guidance of a competent therapist or capable peers.

In a group setting, information can be presented to all clients simultaneously. The therapist can then individually tailor the amount of additional information that is needed for each client. When conducting psychoeducation in a group format, the therapist should be familiar with the process of group interventions as well as each client’s presenting concerns that may affect the group process.

## ***Treatment Goals***

Treatment goals, like the treatment itself, are predetermined. Goals can be general or specific. For instance, a general goal might be to improve overall family functioning by addressing interaction and communication style. A specific goal might be to decrease the frequency of a negative work event. In group formats, the general goal may be similar for each client, but specific goals are idiosyncratic.

## ***Cultural Concerns***

Skilled culturally sensitive therapists are aware of specific cultural concerns that may influence clients’ willingness to seek psychoeducational services, their level of participation, and whom they might wish to bring to sessions as part of their family. Additionally, therapists are aware of issues pertinent to various cultural and ethnic groups. Although this topic cannot be fully addressed herein, some examples of issues to consider are described below.

When providing psychoeducation to Native Americans, it is important to recognize that healers and community leaders are important and therefore may be brought to sessions or might assist in helping the client with the intervention. Asian Americans may prefer a logical and structured approach to treatment, as opposed to a flexible approach that focuses on affective issues. Thus, psychoeducation with its focus on skill building and problem solving may be a treatment of choice. African Americans view the family in broader terms than the “nuclear family” view of Caucasians; therefore, when inviting family members to attend sessions it might be appropriate to include aunts, uncles, or grandparents in the invitation. Similarly, Latino/a families might include extended and nonblood relatives as part of the immediate family system.

When working with immigrant and first-generation minorities, it is important to avoid using children as interpreters, even though they may be more skillful in

the majority language than their parents. This can cause significant problems and complications in exchanging information and impede the outcome of treatment.

## How Psychoeducation Works

### *Therapist's Facilitator Role*

The role of the therapist and the therapist–client relationship in psychoeducation differs from that in more traditional forms of counseling and psychotherapy. In psychoeducation, the therapist serves as facilitator and teacher. While counseling and psychotherapy often focus on remediation of a problem, psychoeducation often pays equal or greater attention to the prevention of problems and the development of strengths. The therapist is largely responsible for determining the goals and activities of psychoeducation and for tailoring the intervention to the needs, motivations, and relative strengths and weaknesses of each client.

### *Stages of Psychoeducation*

Most psychoeducation models have common traits and techniques. Programs typically begin with a comprehensive assessment of client needs, strengths, and weaknesses. This allows the therapist to form a collaborative alliance with the client while gaining valuable understanding of how to best tailor the intervention to fit the client. Building on the client's strengths allows for a focus on the present. The client's past experiences are also incorporated into treatment to identify areas for improvement.

The next stage usually involves a didactic component. This can be fairly structured (e.g., a classroom lecture) or more informal (e.g., group discussion). As transfer of information is a primary function, this phase is often a large proportion of the psychoeducational intervention. Additionally, it is frequently integrated with other steps in a program, rather than presenting the educational information in one stand-alone module.

### *Outcome of Psychoeducation*

Psychoeducation makes a difference in people's lives by enabling them to improve their own (or a loved one's) health, abilities, relationships, or functioning. Psychoeducation attains this goal by providing relevant information to clients about a problem,

illness, or source of distress that is present in their life. Improved knowledge about a problem allows clients to better utilize methods of reacting to it. This leads to a decrease in the stress, conflict, or impairment caused by the problem. Psychoeducation also changes clients' lives by increasing their skills in areas such as communication, problem solving, coping, medication adherence, modification of routines, environment adjustment/management, and social connections.

## PSYCHOLOGICAL WELL-BEING, DIMENSIONS OF

Psychological well-being (PWB) is a theory of positive psychological functioning that focuses on the human capacity to develop, function effectively, and flourish. Theoretical beliefs about what constitutes PWB derive from the philosophical and psychological writings of Abraham Maslow and Carl Rogers.

For Maslow, human behavior was characterized by movement toward self-actualization and, at the same time, limited by more basic processes such as physiological and safety needs. Actualization is attainable only if basic needs were met. Rogers shared the perspective that self-actualization is an inherent possibility and posited that certain interpersonal conditions, such as empathy, respect, and genuineness, facilitate movement toward self-actualization. Thus, consistent with Maslow and Rogers, current PWB theory holds that the development of human potential involves two processes: (1) the inherent human drive for self-actualization, and (2) the creation of the conditions under which that drive might be optimized. These views form the philosophical foundation of counseling psychology.

Three types of studies provide the empirical foundation of PWB theory: (1) factor analytic studies of the organization among individual characteristics of well-being, (2) developmental studies of the changes in well-being across the life span, and (3) neurophysiological studies of the biological correlates of expressions of well-being. One of the more well-developed measures of PWB incorporates six theory-driven dimensions: positive self-evaluations, a sense of continued growth and development, the belief that life is purposeful, the possession of quality relations with others, the capacity to manage one's surroundings effectively, and a sense of self-determination. Data from national surveys, longitudinal studies, and experimental laboratory studies have indicated that PWB indicators are influenced by broad social factors such as age, gender, socioeconomic status, race, and culture; PWB changes as individuals are confronted with life challenges and

transitions; and PWB indicators are associated with diverse health outcomes.

Conceptually PWB is related to subjective well-being (SWB), although not identical to it. SWB is related to judgments of relative happiness and quality of life, whereas PWB has more to do with the management of the existential challenges of life such as having meaning in one's life and growing and developing as a person.

A challenge for mental and physical health professionals is to integrate the psychological evidence concerning the complex, multidimensional nature of PWB into effective primary and secondary prevention programs. The goals are to help normally functioning individuals optimize their lives and to minimize the negative effects of illness or psychopathology. Thus, interventions that are provided to normal functioning people may promote even higher functioning and inoculation against dysfunction. Interventions for people with psychopathology or illness might focus on developing resilience skills; that is, the ability to bounce back to normal functioning or to exceed prior functioning.

Psychologists are presently focused on developing an understanding of the multiple pathways that lead to resilience and how these pathways change throughout life. It is upon this knowledge base that intervention programs to maintain and improve well-being are being constructed.

## PSYCHOMETRIC PROPERTIES

---

Appraisal of human characteristics—such as achievement, ability, proficiency, attitude, belief, or another construct—is routinely accomplished through administration of a test, which is itself often carefully developed and administered by standardized protocols. Examinees and other test users are usually interested only in the results yielded by a test administration; generally they are not attuned to characteristics or technical features of the instrument itself. Still, many persons who use test results realize that the usefulness and appropriateness of test-score interpretation is a direct result of the test's internal characteristics. The internal attributes of a test are technically termed its *psychometric properties*. Psychometric properties are characteristics of tests and other measures of human characteristics that identify and describe attributes of an instrument, such as its reliability or appropriateness for use in a particular circumstance.

Most commonly, psychometric properties provide information about a test's appropriateness, meaningfulness, and usefulness—in other words, its validity. As illustration, suppose a test is advertised as a measure useful for diagnosing a personality disorder such as schizophrenia. The test's psychometric properties provide test makers and users with evidence of whether the instrument performs as portrayed.

Although numerous psychometric properties exist for describing the technical qualities of tests, they are not catalogued into a convenient, definitive list. Instead, whenever a particular feature of a test is described in terms of scientific standards (i.e., not just mentioned in casual conversation), it may be considered as a psychometric property. In its most general usage, therefore, *psychometric property* as a scientific term refers to some essential attribute of the test.

Psychometric properties focus on particular features of a test. Some properties provide evidence as to the quality of the whole instrument, while others provide evidence about its constituent parts, its sections, or even its individual items. For example, when looking at a whole test, a psychometric property could indicate whether the instrument measures a single construct or many. The attribute of a test measuring only a single dimension—or more than one dimension if that is the case—is a psychometric property of the complete instrument. Another psychometric property of the whole test could indicate whether the instrument appraises the target construct equally well for women

and men. This is a psychometric property of sex (or gender) equality. Still other psychometric properties provide evidence of whether a test measures a construct consistently (i.e., reliability). These examples illustrate some common psychometric properties of an entire test: its dimensionality, its equality, and its reliability.

Psychometric properties also exist for individual test questions (i.e., items). Indicators of a particular test item's difficulty, its ability to discriminate among people having differing amounts of the construct being measured (i.e., discrimination), and the likelihood that the correct answer could be chosen by guessing are each a psychometric property of an item.

Another feature for psychometric properties is that they are generally—but not exclusively—expressed quantitatively. Often an index, a coefficient, or some other numerical quantity is given to convey the property. Many students and professionals are familiar with a reliability coefficient, for example. The reliability coefficient is a numerical value. “Reliability” is the psychometric feature for the test, but it is expressed as a quantitative value. So, too, most other psychometric properties are indicated numerically. However, a quantitative value is not always the best means of conveying a particular psychometric property. Validity, for instance, is a complex phenomenon that cannot be meaningfully reduced to a single index or value. Validity is the overarching psychometric property, but a thorough discussion that summarizes an extensive body of evidence is necessary to describe test validity.

It is important to investigate and learn about a test's psychometric properties for two reasons. First, this information is necessary for sound test construction. Psychometricians and other professionals who develop tests need to evaluate and describe how a test functions so that it can be built to a specified level of quality. Second, knowing about the psychometric properties of a test provides evidence that information obtained using the instrument can provide a sound basis for decision making. Psychologists, counselors, educators, policy personnel, and many others often base their decisions, at least in part, on the information garnered from tests. The evidence that supports such decisions is found in a test's psychometric properties. Without knowing how well a test functions, interpretations are suspect.

### Distinguishing Psychometric Properties From Statistics

Psychometric properties are not statistics per se, but they are generally represented by quantitative values.

These values are often calculated using statistical procedures. For example, consider more carefully the notion of *reliability*, which refers to the consistency of measurement. Reliability indicates whether one would obtain consistent information if one applied a testing procedure to a population of individuals or groups on repeated occasions. The idea of how consistently a test operates across several administrations is a psychometric property of a test. A statistical procedure is used to calculate a reliability coefficient or reliability index.

Furthermore, many psychometric properties cannot be expressed through a single value, like a coefficient or index. Many important properties of tests are broad concepts, like their factor structure. Unearthing information about the factor structure of a test typically requires a research design (often a complex design) and information about the factor structure of a test cannot be conveyed by a single value. Thus, statistics are used to calculate values that permit a concise, coherent statement about the psychometric property, but the statistics do not represent the psychometric property. Instead, the concept (e.g., the factor structure for the test) is the psychometric property.

### Test Validity and Psychometric Properties

In a very general sense, all psychometric properties are gauges of a test's validity. *Validity* refers to the degree to which evidence and theory support the interpretations of test scores. One way to think of validity is to imagine how the scores on a test provide information that is useful, appropriate, and meaningful for a particular decision. A decision that is based on supported evidence is valid, and the test is judged to be valid for that particular decision. All psychometric properties provide information (either directly or indirectly) that indicates the test's usefulness for making interpretations, and hence all psychometric properties provide information about a test's validity.

### Types of Psychometric Properties

Table 1 lists some common psychometric properties of tests. Note that the table presents both item statistics and test statistics, the two categories for psychometric properties mentioned above. Under Item Statistics the list includes several indicators of psychometric properties, including item difficulty, item discrimination, and item fit statistics. Each of these characteristics of test items is a psychometric property and each can be

expressed in multiple ways. Item difficulty, for instance, can be a  $p$  value, an item response theory (IRT) fit statistic, or another index not shown in Table 1. The  $p$  value is the proportion (percentage) of examinees that responded correctly to the item on a given occasion. The IRT fit statistic provides an indication of the appropriateness of the question for an examinee when the examiner wishes to administer only items that are theoretically suited to each examinee's overall ability in the proficiency being appraised. Items that are too difficult and those too easy for an examinee are best omitted because they likely provide little information beyond that which can be garnered by presenting only items matched to the examinee's ability. As indicated in Table 1, a variety of numerical values are available for most psychometric properties, each of which has a unique meaning.

Table 1 also indicates a number of properties (e.g., centrality, dispersion, distribution, and reliability) that pertain to whole tests (see the Test Statistics column).

**Table 1** Common statistics used to represent psychometric properties

<i>Item Statistics</i>	<i>Test Statistics</i>	<i>Group Examinee Statistics</i>
<b>Difficulty</b>	<b>Centrality</b>	
p-value	Mean	Sex or gender
IRT difficulty parameter	Std. error of the mean	Ethnic heritage (race)
Delta	Median	Education level
	Mode	Training
	Sum	Employment indices
<b>Discrimination</b>	<b>Dispersion</b>	Experience
Biserial $r$	Std. deviation	Other variables
Point-biserial $r$	Variance	
Polyserial $r$	Range	
Upper v. lower	Minimum	
IRT discrim. parameter	and maximum	
	Std. error	
<b>Other</b>	<b>Distribution</b>	
IRT "fit" stats	Skewness	
Chi square	Kurtosis	
Std. error	<b>Reliability</b>	
	Cronbach's Alpha	
	Test-retest	
	Split-half	
	Other $r$ s	

Again, each psychometric property can have a number of expressions. The psychometric property of centrality provides information about the relative status of the population of examinees on the construct being measured. For example, the population of gifted high school students might be expected to have a relatively high mean, median, mode, and sum, and a relatively low standard error of the mean on a test designed to measure readiness for college. Administration of this test to a sample of gifted high school students, therefore, provides an opportunity to determine whether the test yields results that make sense.

The property of dispersion is close to being the opposite of centrality in tests. Dispersion indicates how variable the examinees are on the appraised attribute. A heterogeneous (i.e., highly variable) group will obtain a wide array of scores; a homogeneous (i.e., very similar) group of examinees will obtain scores that differ only by a small amount.

The psychometric property of distribution refers to the distribution of scores relative to a normally distributed population. In a normal population, the distribution of scores around the median is symmetric. That means that each half of the distribution of scores is a mirror image of the other half of the distribution. When graphed, a normal distribution yields a bell-shaped curve, evidencing zero skew. When the scores are not symmetric, the distribution will be either positively skewed (i.e., have too many low scores) or negatively skewed (i.e., have too many high scores). Kurtosis indicates the peaked nature of the distribution. When the population is symmetric, the number of high and low scores matches the number expected and the peak (i.e., kurtosis) is zero. High-peaked distributions have fewer high and low scores than expected and a kurtosis value greater than zero. Low-peaked distributions have more high and low scores than expected and a negative kurtosis value. Reliability has already been discussed.

Psychometric properties are often displayed in a graphic form when the precise values are less important than conveying the meaning of the properties. Figure 1 is an example that displays a Q-Q plot illustrating the psychometric property of normality in a mathematics test. Normality is another type of expression of the normal values explained for Table 1. The base of the plot is the range of scores on the test (i.e., from below 200 to above 400 in Figure 1). These observed values are plotted against a residual value. The residual value is the difference between the observed value and a value that would be expected if

the population were perfectly normal. Thus, this figure shows how much the observed values deviate from the values that would occur in a normal population.

To interpret normality in a Q-Q plot, notice how the test values (shown as circles) align themselves with the near-45 degree regression line, going from lower left to upper right. In this figure one can see that low-ability examinees (on the lower left near the starting point of the regression line) are not normally distributed. Most of the examinees at the other ability levels are close to normal. However, another slight deviation from normality occurs for the highly able examinees, shown by the circles deviating from the line at the upper right. In test development work, exploring the property of normality for a group of examinees is a common and exceedingly useful procedure. As can be seen in Figure 1, graphic displays of information about psychometric properties often provide clear interpretations of the essential point by eliminating the complexity that occurs when the statistical values are reported in detail.

Figure 2 illustrates a more complicated graphic that conveys a myriad of technical information about a test. The curve line in Figure 2 represents the pattern of responses of a population of examinees to one test item. The lower axis, known as the  $x$  axis or the abscissa, is labeled "Ability" and its scale is symmetric around zero. In other words, a zero on this scale is the median ability of the examinee group. The median

**Figure 1** Graphic illustrating the psychometric property of normality

is the central value; half of the examinees scored higher than the median and half scored lower than the median. The numeric values to the left and right represent standard deviations from the median. Examinees at  $-3.0$  scored very low on the ability being measured and those at  $+3.0$  scored quite high on the ability being measured. The vertical scale on the left, known as the  $y$  axis or the ordinate, ranges from 0.0 to 1.0. This dimension indicates the probability an examinee of that ability level will make a correct response to the item. As can be seen, the probability of a correct response ranges from 0% (0.0) to 100% (1.0). The curved trace line for the item illustrates that persons of low ability have only a low probability of responding correctly to the item. As ability increases, however (moving from left to right along the  $x$  axis), the probability of a correct response to the item grows correspondingly.

Figure 2 also illustrates that the growth is not perfectly linear. If the growth were perfectly linear, the item trace line would be at a 45-degree angle. Instead, the lazy S-shape line illustrates that at very low and very high ability levels, the curve begins to flatten out. That shows that persons in those low and high ability groups all have about the same probability of responding correctly to the item. Thus, the curve tells users that the item is good for distinguishing among people of differing ability levels provided they do not fall into the very high or very low ability group (i.e., their ability is between  $-1.5$  and  $+1.5$  standard deviations from the median). The item is not very useful for distinguishing among people at the lowest and highest ability levels. Still, the overall figure does provide a useful illustration of displaying multipart and refined psychometric properties for tests and their items.

Although Figure 2 contains more psychometric information than can be conveniently explained here, the point to garner from this figure is a realization that psychometric properties are often complex and represent sophisticated concepts, but sometimes they can

**Figure 2** Item Characteristic Curve showing the relation of item difficulty to item discrimination across the full range of ability levels

be represented clearly and simply using graphical displays.

## Evaluation

Psychologists use tests in research and practice to measure constructs that are not readily observable (e.g., agreeableness, need for cognition, and empathy). The scores yielded by a test often provide a basis upon which psychologists make decisions. Because of the importance of test data, it is essential to evaluate the psychometric properties of the instruments psychologists use. The internal properties of the instruments that psychologists use are known as their psychometric properties. An evaluation of the psychometric properties of an instrument allows psychologists to use the instrument with confidence that it will provide reliable, valid, meaningful information that can be used in making decisions.

and symptoms, have as their common thread a significant impairment in mental functioning that causes distress or disability. However, no one sign or symptom is usually sufficient to describe a given mental disorder. Rather, a cluster of related signs and symptoms are necessary that are associated with the distress or disability that is presented. The acquisition of reliable, accurate accounts of those critical features of psychopathology is the goal of any assessment of psychopathology.

Widely known criteria for the various forms of psychopathology appear in the American Psychiatric Association's *Diagnostic and Statistical Manual for Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)* and the World Health Organization's *International Classification of Diseases, Clinical Modification (ICD-10-CM)*. The assessment of psychopathology may at first appear to involve a rather straightforward appraisal of the relative "fit" of these criteria to the particular history and behavioral repertoire of the individual being assessed. This view suggests that appraisal involves little more than decisions about whether one or more sets of these criteria are represented in the information gathered about an individual. If so, the diagnosis (i.e., form of psychopathology) associated with those criteria is assigned to represent the individual's psychological problem(s).

However, the reality is more complicated than the above suggests. Before psychologists can assess the fit of any set of criteria to an individual, they must make a number of decisions regarding the assessment process itself. These include an evaluation of their ability to accurately judge the presence or absence, quality, and quantity of the criteria. In other words, psychologists must evaluate the reliability, validity, and usefulness of the information to be used in assessing the criteria and the context in which the information will be used before the information is accepted for use. Additionally, the perspective taken, for instance, whether the focus is on direct behavioral examples or inferred (i.e., not directly observable) processes, must be taken into account. The ideas and biases of the assessor must be carefully considered. Finally, the information, be it a diagnosis or behavioral description, must be accurately conveyed to the appropriate referring source to actually aid the person being assessed. This has led to the development of a wide range of

---

## PSYCHOPATHOLOGY, ASSESSMENT OF

---

Psychopathology can be thought of as the expression of mental impairment in the form of psychological signs and symptoms. Specific disorders subsumed under psychopathology, while having specific signs

assessment tools that include unstructured and structured interviews, self-report inventories, measures of cognition, projective techniques, behavioral descriptors, and many more.

## The Clinical Interview

### *Unstructured Interviews*

The interview is one of the most basic components of all forms of psychological assessment, including the assessment of psychopathology. Interview formats vary across a continuum from unstructured to highly structured. The unstructured interview is what people most often think about when describing the interview process, though *unstructured* is probably a misnomer. It is essentially a data-gathering process in which information is most often collected face-to-face with a client through an interactive series of questions and answers that can vary greatly from client to client. Typically, questioning follows a format beginning with open-ended questions that can provide information about the content provided, but also about the process the client uses to respond. Questions gradually become more and more close ended during the interview to help fill in needed specific information about the client. The unstructured interview is also used to obtain information from other sources, such as family members or others who can comment on the client's actions.

Whether structured or unstructured, most diagnostic interviews are designed to obtain essential information about many aspects of the person's life situation, such as those listed in Table 1. There are a number of advantages of unstructured interviews, including their flexibility in both the content and the range of information to be sampled. When the psychologist is not limited to what may be asked, or in what manner questions may be asked, important information can be followed up as it unfolds during the interview. Another advantage is the "ecological validity" of the behaviors sampled during the observation of and interaction with the client. Ecological validity pertains to how well the information gathered truly assesses what is important to the client's functioning in the "real" world. Information is more likely to be individualized and specific to the client during an unstructured, and thus unhampered, interview. Disadvantages can include the potential for uneven

and incomplete collection of necessary information by the clinician, as for example when a psychologist spends a great deal of time evaluating reports of depression and fails to fully assess other issues, such as anxiety. Later, comparing only this incomplete set of information with the specific criteria used to make a differential diagnosis can compound an oversight such as this. Nevertheless, a wealth of information can be gathered due to the flexibility of the unstructured clinical interview. Through focused follow-up and probing, many symptom criteria can be directly screened and explored with the client or with collateral sources.

### *Structured Interviews*

In contrast, structured interviews are those that use a specific set of questions to obtain information that is directly related to a set of criteria of particular interest. Structured interviews were developed to reduce the elements of clinical judgment inherent in unstructured interviews. Structured interviews permit the generation of "objective" ratings. This has several advantages. It allows comparisons between cases on essentially the same information. Furthermore, having objective ratings allows psychometric testing of the interview itself in terms of assessing the interview's reliability and validity. A number of structured interviews varying from the global to the specific have been developed for use in diagnosis.

An early, structured-interview strategy was developed by John P. Feighner and colleagues in 1972 to identify the primary psychiatric disorders then described in the *Diagnostic and Statistical Manual (DSM)* of the American Psychiatric Association. In the late 1970s, an influential group of researchers including Robert Spitzer and Jean Endicott altered and expanded these criteria to develop the Research Diagnostic Criteria (RDC). This work, in turn, formed the basis for the Schedule for Affective Disorders and Schizophrenia, or SADS. Over the years, the SADS became one of the most widely used and respected structured interviews for diagnosis, and it has been particularly useful in research settings where consistency in diagnosis is essential. The *DSM* has undergone several revisions and these structured interviews have been modified to reflect the changing criteria for the various forms of psychopathology, leading most

**Table 1** Standard interview information

<i>Type of Information</i>	<i>Examples</i>
Demographic	Date of interview; date of birth; gender; race/ethnicity; education; marital status; birth/rearing origins
Family History	Medical; psychological; educational; cultural milieu; economic milieu
Early History	Birth complications; developmental milestones; early health; early sociability/within-family adjustment
School-Age	Initial and long-term academic adjustment; academic history; achievement/problems; social relationships with family, peers, and authority; health
Adolescence and Early Adulthood	Social relationships with family, peers, others; academic successes/failures; sexual adjustment; legal issues; substance use; career aspirations; health
Adulthood	Interpersonal relationships; satisfaction; employment; career success/failure and satisfaction; health and medical history; substance use; socioeconomic status family support; other support systems
Current Functioning	Mental status; basic and independent activities of daily living—dressing, grooming, house care, cooking, shopping, telephone use, paying bills, dealing with cash, handling a checking account; direct observations—dress/grooming, mobility, gestures, friendliness/approach, effort, cooperativeness; description of typical day
Current Problem(s) and Problem History	Antecedent and precipitant events; description and nature of difficulties; extent and affect of problem(s); coping strategies; sense of efficacy/ability to change
Mood/Affect	General aspects; helplessness; hopelessness; duration/changes
Thought Content	Verbal productivity; verbal continuity; delusions; paranoia; hallucinations; unusual thoughts/fears; impulse control
Thought Processes	Preoccupations; reasoning; insight
Suicidality/Homicidality	Plan; means; intent; history

recently to the Structured Clinical Interview for the *DSM* (SCID) and its revisions. Somewhat in parallel development, the Diagnostic Interview Schedule (DIS) is based on a combined set of criteria from the *DSM* and RDC and it allows diagnosis based on either criteria set.

What these structured interviews all have in common is their dependence on a priori selection criteria for making decisions regarding diagnoses. They differ in their specificity and breadth, and in the amount of clinical judgment and expertise needed to use them effectively. The DIS is very structured, containing very specific questions, and can be used with a high degree of reliability by trained nonprofessionals. The SADS is

semistructured and it requires the extensive use of clinical judgment in making diagnostic decisions. Typically, only experienced mental health professionals use it. The SCID falls somewhere between these extremes, although it is best used by a trained clinician.

Structured and semistructured interviews are currently underutilized in the clinical assessment of psychopathology. This is attributable, in part, to the fact that they were originally developed for use in research. In addition, many psychologists have not been specifically trained in their use. However, the increased reliability of the newer forms of structured interview suggests that psychologists would benefit from incorporating them into their assessment tool kit.

## Instruments Used in Assessing Psychopathology

Many tests have been used to gather information about clients' psychological and mental health other than direct interviews. Tests specific to addressing the presence and severity of psychopathology include both projective methods and objective self-report inventories.

### *Projective Techniques*

The most common projective techniques in use today were actually developed many years ago. They include the Rorschach Inkblot test, developed in 1921, the Thematic Apperception Test, which dates from 1943, and a number of projective drawing techniques.

*The Rorschach Inkblot Test.* The Rorschach Inkblot test is a 10-plate set of bisymmetrical inkblots. By their nature, the inkblots provide an ambiguous set of stimuli to the client. For each individual plate, the clients are simply asked to tell the assessor what the inkblots remind them of. Thus, without further instruction, clients are placed in a position that necessitates the use of their own personal perceptual experiences to place an organizational structure and context onto these otherwise ambiguous stimuli. In this way, the organization of the material becomes a behavioral example of the way clients approach and organize the world with which they interact.

The Rorschach has been used extensively and many categories of response type have been developed, particularly regarding the determinants of what goes into individual percepts. These include the use of form, color, symmetry, and even textural cues. The core elements needed to interpret any Rorschach response are *what* the response is, *where* it is located, and *why* or what makes it look that way. The interpretation of these elements as they represent organizational strategies and methods has been used to provide information about people's interpersonal style, motivation, emotional processes, and even their cognitive abilities. While controversial because of arguments regarding its reliability and validity, the Rorschach is still commonly used by many clinicians. Effective use of the Rorschach requires extensive training in its administration and, in particular, in the interpretation of responses to the Rorschach materials.

*Thematic Apperception Test.* The Thematic Apperception Test (TAT) was originally developed in conjunction

with Henry Murray's need-press theory of personality. It is made up of a series of pictures that show characters in a variety of ambiguous situations. Examinees are instructed to make up an oral story about each picture. The rationale underlying the TAT is that the stories told by examinees in their search for some meaning in the ambiguous pictures represent projections of the examinees' past experiences and present needs. Thus, somewhat similar to the Rorschach, the test uses ambiguous stimuli to elicit samples of the ways the examinee organizes the world. Unlike the Rorschach, the TAT makes use of a sample of specifically focused instructions that are repetitive across picture stimuli. Thus the examiner can elicit samples of similar or "thematic" situations by selecting particular subsets of cards to present. The examiner follows an interpretive strategy that focuses on the characters and settings in the stories told by the examinee, as they are likely to reflect the examinee's placement of self into them. The protocol data thus elicited are presumed to provide a representation of personality content and character structure.

*Projective Drawing Tests.* Projective drawing techniques used in the assessment of psychopathology are generally one of two types, Draw-A-Person or Draw-A-House. In both, clients are asked to draw freehand one or more pictures of themselves, significant others, their family, their home, or a similar object. The basic premise is to provide an environment that elicits information about a person's feelings about the *targeted* stimuli (e.g., self, family member). The examinee is thought to project his or her own perceptions of these targeted stimuli onto the drawings. Assessment relies on an accurate interpretation of the elements of the drawings as they relate to the client's thoughts and feelings. Artistic talent is irrelevant. Rather, it is the configuration and style of the elements that is evaluated. For example, poor drawing symmetry may be reflective of insecurity or inadequacy, low levels of detail may be suggestive of withdrawal or depression, and large head size may be suggestive of expansiveness and aggression.

*Projective Test Summary.* Projective tests have had a long history of use in the assessment of psychopathology. However, the reliability and validity of projective tests has been a long-standing controversy. At a minimum, the use of these tests calls for significant training and experience, and even the most skilled

clinician must take great care to avoid potential judgment biases.

### **Objective Self-Report Inventories**

Objective self-report inventories have been widely used for close to 70 years and continue to enjoy great popularity. Two of the most commonly used measures are the Minnesota Multiphasic Personality Inventory (MMPI) and the Millon Clinical Multiaxial Inventory (MCMI).

*The Minnesota Multiphasic Inventory.* The MMPI-2 was originally designed as a diagnostic tool to identify specific *DSM* disorders. However, the findings from more than six decades of research on the instrument have expanded its use to include multiple behavioral and symptom correlates based on patterns of responding across its many subscales. In brief, the MMPI-2 consists of 557 true/false items that are scored to yield scores on 10 primary clinical scales. These primary scales retain their original labels (e.g., Hypochondriasis, Depression, Hysteria, Psychopathic Deviate), however, they are no longer interpreted as stand-alone scales but as reflective of a pattern of symptoms and behaviors shared by common groups.

The MMPI-2 also contains several “validity” indexes, including the K (Correction) scale and the L (Lie) scale, and a host of content-based and supplementary scales. Content-based scales are those that have been composed of items that, at face value, appear to represent domains of similar content. Examples include scales of Anxiety, Obsessiveness, Social Discomfort, and Family Problems. Supplementary scales are those that have been created by combining items, usually based on statistical rationales, to represent an area of clinical interest. Examples of supplemental scales include Repression, Ego Strength, Marital Distress, and Gender Role Identification.

Current interpretation strategies usually revolve around pattern analysis of scale elevations. Specific sets of scale score patterns are then associated with likely behavioral response patterns that have been seen in others with similar patterns. These symptom sets are then used to determine the fit of the examinee to specific diagnostic criteria. For example, people who obtain high scores on both Clinical Scale 2 (Depression) and Clinical Scale 9 (Introversion) have been shown to often be ruminative, worried about achievement, and self-centered. They often report

feeling tense and anxious, and may engage in episodes alternating between excessive activity and apathy. They are sometimes diagnosed with depression or bipolar disorder.

The MMPI-2 has been criticized along several grounds. Given that it was originally established to identify severe psychopathology, it is viewed as limited in its ability to describe less severe pathology or normal personality characteristics. Additionally, despite its “objective” standing, the practice of interpreting patterns of scale scores leaves it open to clinical biases similar to those of the projective techniques. Nevertheless, the MMPI-2 has been shown to be extremely helpful in the diagnosis of a number of mental disorders, and it remains an efficient method of gathering diagnostic information.

*Millon Clinical Multiaxial Inventory.* The newest iteration of the MCMI, the MCMI-III, is a 175-item, true/false self-report questionnaire designed to assess psychopathology, personality characteristics, and emotional adjustment. It is used for both diagnosis and character descriptions. Originally developed in 1977, the instrument has gone through several revisions, the most recent being in 1994. It currently includes 24 scales that are closely associated with the *DSM-IV-TR* diagnostic categories. As with the *DSM-IV-TR*, these scales are grouped in two broad categories. Axis I scales are those that are thought to reflect primary disorders of thought such as depression, anxiety, and schizophrenia. Axis II scales are those that are thought to reflect more enduring trait characteristics and are represented by the personality disorders such as borderline personality disorder or avoidant personality disorder. The MCMI-III includes four Modifying Indexes—Validity, Disclosure, Desirability, and Debasement. These scales are used to either invalidate the test due to inappropriate responding (Validity Index) or to modify the existing clinical scales by taking into account additional variables including the examinee’s response openness (Disclosure Index), response defensiveness (Desirability Index), and symptom exaggeration (Debasement Index).

The MCMI is based on Theodore Millon’s personality theory, which describes personality traits in terms of relatively enduring patterns of interpersonal coping styles. Personality styles evolve from the interaction between a person’s perceived sources of reinforcement and his or her avoidance of pain. These factors are moderated by the person’s tendency to

actively or passively manipulate his or her environment to obtain favorable outcomes. For example, the categories of Pleasure versus Pain and Self versus Other are activated by either an Active or Passive way of obtaining satisfaction. According to Millon, all personality disorders are derivations of these combinations. Millon would thus identify an avoidant personality as influenced by sensitivity to pain as a negative reinforcer, an emphasis on the self as the source of reinforcement more than others, and using an active strategy to expose oneself to these factors.

Millon described the more severe clinical syndromes (e.g., *DSM* Axis I disorders such as schizophrenia or bipolar disorder) as acute reactions. Pathology is associated with ingrained personality styles that have become extremely rigid and inflexible, leading to greater impairment. Thus, when interpreting MCMI-III profiles, the psychologist will first pay attention to the Axis II (enduring trait) scales, followed by the Axis I scales.

The MCMI-III is also unique in its reliance on “base rates” of known diagnostic disorders to establish fit. In other words, the MCMI-III takes into account the prevalence of any given diagnostic category (e.g., antisocial) within the general population. Relatively rare disorders need a greater number of scale items to indicate their presence compared to more “common” disorders.

Because of the overlap of the MCMI-III with the *DSM*, its diagnostic interpretation is relatively straightforward. Overall, the MCMI-III has been shown to be predictive of *DSM* diagnostic categories.

**Additional Self-Report Inventories.** Other self-report inventories used by psychologists include the California Psychological Inventory (CPI), the Sixteen Personality Factors test (16PF), and the Psychological Assessment Inventory (PAI). Developed by Harrison Gough, the CPI 434 is a 434-item true/false test similar in construction to the MMPI but developed to identify a more “normative” range of personality characteristics. It currently has 20 scales that fall into 4 broad categories: self-related, social-related, achievement-related, and interest-related. True to its intent, the CPI 434 provides data on personality style rather than personality disorder. Thus, it is used most often in industrial-organizational settings and employment settings and is popular in executive and leadership identification. There is also the CPI 260, which is a shorter version of the CPI 434.

The 16 PF was developed to measure the 16 primary factors that personality psychologist Raymond Cattell used to describe the personality characteristics of individuals. The 16 PF, now in its fifth edition, consists of 185 multiple-choice items that form 16 bipolar clinical scales. Bipolar scales yield scores that range from one extreme to the other on the dimension being measured. For example, the Reasoning scale is anchored from *concrete* to *abstract*; the Emotional scale is anchored from *reactive* to *emotionally stable*. In addition, global scores on Extraversion, Anxiety, Tough-Mindedness, Independence, and Self-Control are derived from the clinical scales. The test has been widely used to measure both normal and deviant personality styles. It is used in traditional clinical settings for diagnostic and treatment decisions, as well as in vocational settings.

The PAI is a 344-item inventory that consists of items having four response options (*false*—not at all true, *slightly true*, *mainly true*, *very true*). The PAI consists of 4 validity scales (Inconsistency, Infrequency, Negative Impression, Positive Impression), 11 scales directly assessing criteria associated with major mental disorders (e.g., depression, mania, and anxiety), 2 scales evaluating interpersonal relations (Dominance and Warmth), and 5 scales that yield treatment-based predictions (e.g., Suicidal Ideation and Treatment Rejection). It has been validated on both clinical and nonclinical populations and can be used with either population. The instrument yields separate standard scores (in this case, *T* scores) for comparison to both populations. The PAI has gained solid use over the approximate 15 years of its existence and is relatively easy and straightforward to interpret.

### **Behavioral Assessment Tools**

A basic tenet of behaviorism and learning theory is that all behavior is learned. That includes pathological behavior. Some of this learning occurs as a result of stimulus-response relationships that are learned over time within a particular environmental context. Other behaviors are learned vicariously (i.e., by observing others and copying their behavior). The behavioral assessment of psychopathology relies on this basic tenet and focuses on a quantitative approach to describing problem behaviors that make up psychopathology. Thus, the major methods of behavioral assessment focus on the size, the strength, and the number of the problem variables assessed. As in other assessment methods, the behavioral assessment of psychopathology

focuses on acquiring reliable and valid data. However, the data are typically restricted to directly observable or at least verbally describable phenomena that can be quantified. Behavioral assessment tools are quite varied and they are often quite specific and tailored to the circumstances of the individual.

Behavioral interviewing is a primary tool of behavioral assessment. Behavioral interviews focus on operationally defining problem behaviors and on elucidating the relationships between those behaviors and precipitating events (antecedents) and resultant consequences. Since the ultimate goal of behavioral assessment is to change problem behaviors, the focus tends to be on the more immediate antecedents and consequences of problem behaviors. Less attention is given to obtaining detailed historical information about life events such as childhood experiences.

Behavioral assessment also emphasizes the direct observation of problems and the use of behavioral assessment checklists. Behavioral checklists are tools that assist in quantifying specific behaviors. They are typically short, specific to particular disorders, and easy to complete. Behavioral checklists are most often completed by clients, but can be used in a question-and-answer format by an examiner. They can be extremely helpful for gathering self-reported symptom information that can be compared to a normative distribution.

Examples of widely used behavioral checklists include the Beck Depression Inventory (BDI) and Beck Anxiety Inventory (BAI), and the State-Trait Anxiety Inventory (STAI). The second edition of the BDI (BDI-II) is a 21-item self-rating scale consisting of items that cover a broad range of depression-related symptoms. Like most behavioral checklists, it takes only a few minutes to complete and because the responses represent examinees' ratings of specific behaviors, it provides a description of the kinds of symptoms a client reports. The BDI and other checklists can be summed up for comparison to different populations, and thus it gives an indication of the severity of depressive symptoms. The BAI is a similar tool that assesses the presence and severity of specific symptoms of anxiety.

The STAI is a well-established behavioral checklist developed by Charles Spielberger that focuses on behaviors related to both stable, relatively enduring trait-based features of anxiety, and situational, state-based features of anxiety. The State Anxiety and Trait Anxiety scales each consist of 20 items that offer four response alternatives (*not at all*, *somewhat*, *moderately so*, *very much so*) for describing the extent to which

features of anxiety are personally descriptive. The State scale asks respondents to answer in terms of how they feel at the moment, while the Trait scale directs them to answer in terms of how they generally feel. The STAI is easy to complete and has been shown to be a good indicator of self-perceived anxiety.

The Symptom Checklist-90-R (SCL-90-R) is a broader-based tool that uses relatively few items to form behavior-based scales that have been associated with specific diagnostic categories. Developed by Leonard Derogatis, the SCL-90-R scales assess nine primary symptoms (e.g., depression, hostility, obsessive-compulsive, psychoticism) and three global indexes of overall distress. Its relative comprehensiveness, brevity, and easy-to-use checklist format make it a useful tool for psychologists.

### Clinical Judgment in Assessing Psychopathology

It is critical that psychologists be sure that the information they are obtaining provides an accurate reflection of the client's circumstances when gathering assessment information. Most psychologists make their own decisions regarding the accuracy, impact, relative weight, and usefulness of the information they gather, but the ability of clinicians to do this has been a point of controversy. In 1954 Paul Meehl questioned the ability of psychologists to make accurate inferences (i.e., predictions) from the assessment information they obtain. Since that time numerous studies have shown that the use of statistical algorithms to make predictions yields greater accuracy than clinical judgment.

Danny Wedding and David Faust have described a number of clinical biases that lessen the accuracy of an assessment of psychopathology. These include hindsight bias, or the tendency once something is known to believe that the outcome could have been more easily predicted than is the actual case. Confirmatory bias is the tendency to look for evidence supporting one's early hypotheses while tending to overlook evidence that would be contrary to those hypotheses. Overreliance on salient data is another bias often attributable to the assessment process. This occurs when one pays greater attention to information that appears more "impressive" and ignoring less dramatic information. The underutilization of base rates is another limitation to which psychologists are prone. Base rates (i.e., the prevalence or frequency with which an event occurs in

the population) provide important information about the likelihood of observing a given disorder, but psychologists often ignore base rate data. Another judgment shortcoming Wedding and Faust point out in assessment is the common failure to analyze covariation. By this they mean that the likelihood that an observed relationship (e.g., an increase in depressive features and a new marriage) could be influenced by an additional factor (e.g., a job change). Finally, the cognitive limitations inherent in all persons, (e.g., limited working memory capacity, limits in complex processing, and inaccuracies of information manipulation) also limit the ability of psychologists to make accurate predictions from assessment data.

Skilled psychologists are aware of these biases and take steps to minimize them. Specifically, they use comprehensive structured or semistructured interview techniques and assessment tools that have been empirically proven to be both reliable and valid. This reduces the likelihood that relevant information will be overlooked, resulting in an overreliance on narrow description. To minimize hindsight and confirmatory biases, they give careful attention to data that both support and do not support tentative conclusions. They base diagnoses on specific criteria to reduce the influence of cognitive biases and stereotyping due to factors such as gender, age, and ethnicity. In addition, they recognize that memory is a reconstructive process that provides numerous opportunities for biases to influence psychologists' conclusions and minimize this problem by attempting to minimize their reliance on their own memory. Attending to base rates and understanding the population with which psychologists work can effectively guide expectations regarding the amount of evidence necessary for a diagnosis and insuring data collection specific to that population. Finally, skilled psychologists seek feedback regarding the accuracy and usefulness of their judgments to help shape and refine their diagnostic process.

Research has shown that actuarial-based assessment tools have almost uniformly proved to be more accurate than clinical judgment alone. Nevertheless, the clinical assessment of psychopathology has remained a judgment call. Thus, it is vitally important that psychologists base their judgments on the most reliable and valid tools available, and that they understand the limitations of their judgments.

## PSYCHOPHARMACOLOGY, HUMAN BEHAVIORAL

---

Drugs play an increasingly large role in civilization, and especially among the patients or clients who are seen by mental health professionals. The drugs that counselors may encounter fall into two major categories, therapeutic and recreational. Therapeutic drugs may facilitate the clinical goals of the patients, but can also present unique problems that must be addressed in the therapeutic setting. Drugs used for nontherapeutic reasons may contribute to the problems of the patient, or otherwise interfere with the therapeutic relationship. The major classes of medical

and nonmedical drugs that counselors are likely to encounter in their practice are discussed in this entry, including their primary effects and side effects, and the clinical issues that may arise.

### Therapeutic Drugs

The most widespread therapeutic drugs include those used to treat anxiety disorders, depression, psychotic illnesses, and attention deficit/hyperactivity disorder (AD/HD). Agents used in treating these disorders can interact with psychosocial treatments. A psychotropic medication provides symptomatic relief that may increase the effectiveness of psychosocial treatment. For example, a patient suffering from an acute psychiatric illness may be withdrawn, apathetic, and unable to interact with the counselor. Medications ameliorate these symptoms so that the patient can then develop the skills and abilities necessary for a functional recovery. On the other hand, under some circumstances psychotherapeutic agents may hinder the delivery and application of psychosocial treatment, as in the case of drugs with severe sedative and amnesia-causing actions. Therefore, counselors consider the side effects of common psychotherapeutic drugs, and the possibility that these effects may present further psychological problems that must be addressed.

Anxiolytic (antianxiety) agents are among the most frequently prescribed psychiatric medications. Benzodiazepines, such as diazepam (Valium) and alprazolam (Xanax), are widely used for the treatment of generalized anxiety and panic disorders. At low doses, these drugs produce calming effects and mild sedation. Therefore, they are prescribed to treat both daytime anxiety and insomnia. At high doses, these drugs prolong sleep and, in the presence of other central nervous system (CNS) depressants, they can cause life-threatening respiratory depression (slowed breathing). The main side effects of these drugs are drowsiness, confusion, and impaired coordination. Benzodiazepines also have strong memory-impairing effects.

Although these drugs are effective for a variety of anxiety-related problems, there is some concern regarding their long-term use and potential for dependence. Some patients report that physical and psychological withdrawal symptoms make it difficult to stop taking benzodiazepines. Patients may also experience short-term rebound anxiety after stopping their medication. The risk of dependence on benzodiazepines is greater in individuals with severe mental illness or

co-occurring substance-use disorders. Nevertheless, the long-term risk-benefit ratio of benzodiazepines in other patient populations remains controversial. Newer nonbenzodiazepine anxiolytic agents, such as sertraline (Zoloft), appear to have a better risk-benefit ratio.

Antidepressants are also widely prescribed, and may be used with psychosocial treatment. Currently, the first line of treatment for major depression are selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac), sertraline (Zoloft), and escitalopram (Lexapro). These drugs may also be used to treat anxiety disorders such as panic disorders and obsessive-compulsive disorder.

Antidepressant effects of SSRIs are typically manifest only after at least 2 weeks of treatment. Side effects include nausea, anorexia, insomnia, sexual dysfunction including loss of libido and failure of orgasm, and increased suicidal thoughts in the first month of treatment. The use of some SSRIs with children and adolescents is contraindicated as there is some evidence that they increase suicidal thoughts in this age group.

Another class of agents used to treat depression is tricyclic antidepressants, although their use is usually reserved for individuals who do not respond to treatment with SSRIs. Tricyclics nonselectively block reuptake of both serotonin and norepinephrine and are more likely than SSRIs to produce side effects, including sedation and impaired psychomotor performance on tasks requiring attention, low blood pressure, confusion, and difficulty coordinating movements. Overdose with tricyclics is dangerous, particularly in combination with alcohol.

An important category of psychiatric medications is antipsychotic drugs, also called neuroleptics. These drugs are used to treat schizophrenia, psychotic depression, and mania. The two major classes of neuroleptics are referred to as *typical antipsychotics* (e.g., haloperidol such as Haldol), and *atypical antipsychotics* (e.g., clozapine such as Clozaril and, risperidone such as Risperdal). These drugs produce immediate sedation and are considered major tranquilizers. However, their antipsychotic action is delayed and requires up to 3 weeks treatment before effects are seen.

Despite their beneficial effect in reducing psychotic symptoms such as thought disorders, hallucinations, and delusions, these drugs also produce sedation, apathy, and reduced initiative and cognitive functioning. Patients' dislike of these side effects may lead to nonadherence with medication and relapse.

These drugs also produce motor disturbances including Parkinson-like tremor, muscular rigidity, and sudden spasms of the head, neck, limbs, or trunk. These motoric effects are more pronounced in typical antipsychotics than in atypical ones.

Stimulant medications used for the treatment of AD/HD are a further class of therapeutic agent used in the clinic, especially with children and adolescents. These include methylphenidate (Ritalin, Concerta), amphetamine (Adderall), dextroamphetamine (Dexedrine), and atomoxetine (Strattera). These drugs reduce hyperactivity, increase attention span, and improve concentration, vigilance, and activity in AD/HD patients. However, they also have some adverse effects, including palpitations (abnormal heart beats), insomnia, weight loss, tics, and impotence. These agents also have a potential for abuse. Although they do not cause euphoria or feeling high at therapeutic doses, they can produce cocaine-like effects when crushed and injected. Despite concerns to the contrary, there is little evidence that treatment with AD/HD drugs leads to later drug abuse. Children treated with stimulant medications are *less* likely to develop later substance abuse problems.

### Abused Drugs

Agents used recreationally, including illegal substances and prescription medications, can adversely affect counseling care. Problematic drug use can generate psychological problems, exacerbate underlying psychiatric disorders, and interfere with attempts to change behavior. Therefore, screening for drug abuse is essential as part of the initial evaluation of any new client.

Psychiatric diagnoses of substance abuse and dependence are made using specific objective criteria listed in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*. The main criteria for substance abuse are drug use that interferes with performing work, domestic, or social duties; exacerbates interpersonal or social problems; causes legal problems; and/or is used in a situation that is physically dangerous. The criteria for substance dependence include additional features such as tolerance or withdrawal, a loss of control over use, and persistent use in spite of knowledge of its detrimental effects. Briefer diagnostic tools are available to the clinician, such as the four-item CAGE questionnaire used to assess alcohol abuse (i.e., "Have you ever felt you should Cut down on your

drinking?"; "Have people Annoyed you by criticizing your drinking?"; "Have you ever felt bad or Guilty about your drinking?"; and "Have you ever had a drink first thing in the morning (as an 'Eye opener') to steady your nerves or get rid of a hangover?").

Counselors may take several steps to address the issue when drug use has been identified as a problem. The first and traditionally the hardest step is to help the individual to recognize that his or her pattern of use causes or intensifies existing problems. The second step is to work with the client on his or her motivation to change. Only then can steps be taken to decrease use. If dependence exists, the individual may be referred to an addiction service. For example, in the case of severe alcoholism, or dependence on opiates and sedative drugs, withdrawal symptoms can be life threatening and may require inpatient treatment. Counselors' knowledge of the current status of psychosocial and pharmacological treatments available to treat substance abuse enables them to select the approach that is most appropriate for the client. Options may vary according to the specific drug of abuse. Because drug dependence is a chronic, relapsing disorder, most substance abuse clients require continued monitoring, even after long periods of successful abstinence. More broadly, this means it is important for counselors to ascertain whether *any* client has previously had a drug problem, whether or not he or she presents with drug-related complaints. The most prevalent drugs of abuse are alcohol, marijuana, stimulants, sedatives, and painkillers.

Alcohol is one of the most widely accepted forms of recreational drug use. Alcohol is a CNS depressant that was used as a general anesthetic until the late 19th century. At low doses, it produces feelings of well-being, reduces anxiety, and reduces behavioral and social inhibitions. At moderate doses, it impairs motor function and reaction times. Higher doses of alcohol produce severe motor and sensory depression, and at toxic concentrations unconsciousness, coma and lethal respiratory depression may occur. The withdrawal syndrome associated with alcohol dependence is severe and can cause fatal seizures.

Marijuana is derived from the *Cannabis sativa* plant, which contains cannabinoid compounds such as delta-9 tetrahydrocannabinol (THC), cannabidiol, and cannabinol. Cannabinoids typically increase heart rate and blood pressure and produce feelings of relaxation, heightened sensory awareness and distorted perception of time. However, marijuana also produces

impairments in memory and some individuals experience panic reactions and paranoia, even at relatively low doses. Long-term use may produce dependence, and there are anecdotal reports that prolonged use can produce apathy (“amotivational syndrome”) or exacerbate psychotic symptoms.

Stimulant drugs, such as amphetamine, methamphetamine, Ecstasy, and cocaine, are frequently used as recreational drugs by young adults. These agents stimulate the CNS, thus increasing motor activity and producing excitement. At high doses, stimulants increase body temperature and produce repetitive stereotyped behaviors, insomnia, and anorexia. Repeated use of high doses of stimulants may produce a form of psychosis that closely resembles schizophrenia. Anxiety and paranoia are common adverse effects associated with the use of stimulant drugs.

MDMA (3,4 methylenedioxymethamphetamine), or Ecstasy, is a synthetic drug that has both stimulant and hallucinogenic properties. Throughout the 1990s, it was a popular drug in the youth culture for its euphoric and energizing effects and enhancement of tactile sensations. MDMA also increases empathy, but there have been reports that long-term use is associated with depression.

Caffeine, which is also a mild stimulant drug, is the most widely consumed psychoactive drug in the world. It is present in coffee, tea, soft drinks such as Coca-Cola, and chocolate. Although low doses are benign, increasing alertness and decreasing fatigue, caffeine can also produce nervousness at high doses or even at low doses in sensitive individuals. Caffeine may worsen existing anxiety disorders and precipitate panic attacks, particularly in individuals with panic disorder.

Sedative drugs, such as the barbiturates amobarbital (Amytal) and phenobarbital (Nembutal), are misused for their intoxicating effects. Typically, they are used in conjunction with other drugs, either to augment the pleasurable effects of those drugs (e.g., alcohol) or to counteract their unpleasant effects (e.g., to decrease nausea among opiate users). Low doses of barbiturate drugs produce relaxant effects similar to alcohol and higher doses impair motor coordination and produce sedation. Barbiturate overdose produces unconsciousness and death via respiratory failure. The risk of physical dependence on barbiturates is high even with relatively short-term use of high doses, and abrupt withdrawal may be fatal. Benzodiazepines are also used recreationally by a relatively small subset of young adults. As previously noted, despite public

concern about their potential for misuse, the prevalence of abuse or dependence is low in clinical use and their safety profile is excellent.

Another class of abused drugs is opioids, such as heroin, oxycodone (OxyContin), and codeine (Tylenol with codeine). These drugs are CNS depressants that produce feelings of euphoria, but also sedation, nausea, vomiting, and constipation. Overdose with opioid drugs is particularly dangerous because it can result in coma and death by respiratory failure. Tolerance to these drugs develops rapidly and users must increase the dose to obtain the same effect. Physically dependent individuals who discontinue opioid use may experience irritability, weight loss, fever, nausea, diarrhea, and insomnia. Psychological dependence produces an intense craving for the drug upon abstinence that lasts for many months after detoxification. Oxycodone is an opioid drug used to treat pain that is twice as potent as morphine, and recently there has been a sharp rise in abuse and diversion of this drug for illicit use.

Hallucinogenic drugs, including d-lysergic acid diethylamide (LSD), mescaline, and psilocybin, cause sensory distortion or hallucinations that may be visual, auditory, tactile, gustatory, and/or olfactory in nature. The positive subjective effects of hallucinogens include stimulation, increased sensory awareness, and increased associative and creative thinking. Users describe their experiences as enlightening and life changing. There have been trials of hallucinogenic drugs to treat alcoholism and the pain and depression associated with terminal cancer. However, reactions and experiences vary across individuals and hallucinogens are equally likely to cause acutely unpleasant sensory experiences. Adverse effects of hallucinogens include panic reactions, prolonged psychosis, depression, and so-called flashbacks whereby transient perceptual disturbances recur weeks or months after intoxication.

## Counseling Considerations

Mental health professionals licensed to prescribe drugs and those who specialize in the treatment of substance abuse are familiar with the beneficial effects and adverse side effects of the most commonly used drugs. They are knowledgeable about the advantages and potential drawbacks of treating psychological disorders using a combination of psychopharmacological and psychotherapeutic interventions. Potentially, the use of drugs may increase the effectiveness of psychosocial

treatment. They can reduce psychiatric symptoms so that patients are more available to treatment, and in some disorders may strengthen attention, speech, and memory. In turn, counseling can improve the relationship between the patient and care provider and improve treatment compliance. On the other hand, drugs can interfere with the long-term resolution of psychological problems because they relieve the immediate symptoms and reduce the patient's motivation to confront the underlying problems. Furthermore, they may produce psychological dependence or intensify a patient's perceptions of being ill. Thus, there are complex considerations surrounding the use of therapeutic drugs in a counseling context.

Mental health professionals are likely to encounter clients who use drugs nonmedically, and must make decisions about the extent to which this drug use contributes to the presenting problems. Recreational drug use is very common, especially among people with high levels of life stress, adjustment difficulties, and life transitions, who are most likely to seek counseling. Therefore, the counselor should always include a thorough assessment of the level of drug use to determine whether the use is in itself a source of problems, whether it contributes to other existing problems, and whether it might interfere with the counseling process.

## PSYCHOTHERAPY, OUTCOMES OF

**See** OUTCOMES OF COUNSELING  
AND PSYCHOTHERAPY

---

## QUALITY OF LIFE

---

Quality of life (QOL) is a concept that has been considered vital to counseling and psychotherapy services since the profession began. Clients seek counseling services to improve their QOL, and so QOL is of critical importance to both process and outcome in therapy. Although more than 20,000 articles referencing QOL appeared in the psychological literature between 1980 and 1994, a consensus definition of QOL remains elusive. The concept is often assumed to be self-explanatory, but it is used in varying ways by different authors and professions.

The World Health Organization first defined QOL as multifaceted, consisting of total well-being in social, physical, and mental functioning. Medical definitions of QOL, derived from this early work, emphasize the capability for a full and active life by patients with physical illness; in other words, the individuals' ability to live fully without restrictions on their everyday activities.

Recent works in psychology have added additional key observations. First, since *quality* denotes excellence, *quality of life* at its most basic reflects the degree to which an individual *experiences excellence* in the major domains of his or her life. Second, QOL involves more than physical comfort and the absence of pathology. QOL represents a degree of excellence in which an individual's personal experience and functioning are excellent in social, psychological, cognitive, and physical ways. Positive psychology distinguishes between the "pleasant" (enjoyable) life and the "meaningful" (engaged) life, and it suggests that the highest degree of QOL is gained from a life

*fully engaged* in sustaining meaningful activities. This latter reasoning dates to Aristotle's definition of happiness (often paraphrased by John F. Kennedy) as "full use of one's faculties along lines of excellence."

QOL exists on a continuum that ranges from the lowest to the highest degrees of subjective experience and excellence in life. QOL can be reliably measured via self-report; hundreds of scales have been developed to measure aspects of QOL. Each measure typically selects specific dimensions of QOL that involve emotional, physical, or cognitive functioning. Subjective estimates of QOL may also be made related to a specific client group or "referral reason" (e.g., QOL in pediatric, medical, or oncological care). Qualitative assessment procedures (most often in the form of an interview) also have been developed.

Multiple subdisciplines of psychology, counseling, and medicine use the construct of QOL in three common ways: (1) as a construct denoting overall well-being, (2) as a factor for assessing a person's satisfaction with his or her life situation (even during serious or chronic illness), and (3) as an outcome variable for evaluating the effectiveness of counseling and therapy efforts to improve a person's life. Quantifying and refining the concept of QOL will further enhance practitioners' ability to evaluate therapeutic interventions, and, by focusing clients' attention on what is right with their lives, these efforts may be therapeutic in and of themselves.

## **RATIONAL EMOTIVE BEHAVIOR THERAPY**

---

Albert Ellis first demonstrated and introduced his innovative rational-emotive therapy (RET) in 1957. In 1993, Ellis revised and expanded the scope of his theory, creating rational emotive behavior therapy (REBT). REBT resulted from Ellis's response to the frustration he experienced as a psychoanalyst when his patients were not improving using traditional psychoanalytic techniques. Ellis found that patients seemed to improve more rapidly when he was more active and direct in his methods. The perceived lack of efficacy of psychoanalytic treatment caused Ellis to return to his philosophical roots in Greek, Roman, and ancient Asian philosophy and seek a more effective form of therapy. These philosophies laid the foundation for REBT, which states that people are disturbed not by things, but by their views of those things.

Ellis focused on people's cognitions as the sources of their psychological distress and believed there were two basic biological tendencies in how humans think. The first is that humans have a biological tendency to think irrationally and in a dysfunctional manner. This is based on humans' predisposition to think "crookedly," and is supported by the observation that irrational thinking is so prevalent despite the individuals' attempts to think rationally. The second biological tendency is that humans also tend to work toward changing their dysfunctional thinking and acting. Humans have the ability to recognize when their irrational thoughts are causing a disturbance, the ability to see

that a change can be made to alter the irrational thinking, and the ability to actively work toward changing the irrational thoughts through cognitive, emotive, and behavioral methods. REBT works with that ability in order to help individuals identify and change their irrational belief systems to more rational ones. Overall, the image of the person in REBT is one of optimism. REBT has a basic proposition that people have goals, desires, and purposes in life that generally can be described as striving for happiness, a long life, self-actualization, success, approval, and comfort. A healthy person sees these goals and desires as options, not absolute givens that must occur.

Understanding this therapeutic approach can be best explained by going through the ABCs of REBT. An Activating Event or Activating Experience (A) is something that happens to a person. For example, a student receives a bad grade on a paper. People typically assume the Activating Event causes the emotional or behavioral Consequence (C) (perhaps the student's feeling of being a complete failure and withdrawing from the class, in this example). However, the Consequence is not a direct result of the Activating Event, but rather a result of the Belief (B) system the person has about the Activating Event. For example, if the Belief about getting a good grade on a paper is that it would be pleasant and rewarding to get such a good grade, but not mandatory, the resulting Consequence could be disappointment or frustration when receiving the bad grade and perhaps a resolve to do better in the future. However, if the person's Belief is "I must get a good grade because anything less than perfect means that I am stupid and will never succeed in life," then

the Consequence would be despair and depression when the bad grade was returned. Therefore, it is not the Activating Event that results in the Consequence, but the Belief, which is based on biological or genetic predisposition, constitutional history, prior interpersonal and social learning, and predisposed and acquired habit patterns.

As mentioned earlier, just as humans have a natural propensity to be rational and straight thinking, they also have the propensity to be “crooked-thinking” creatures. Irrational beliefs differ from rational beliefs in two distinct ways. First, they are absolute or dogmatic and are expressed through rigid forms of “must,” “should,” “ought,” and “have to.” Second, irrational beliefs lead to negative emotions that interfere with the achievement of goals. REBT posits that the irrational beliefs are centered on the human tendency to make demanding and commanding statements about what *should* and *must* happen in life and that these things *absolutely* and *necessarily* must occur to obtain the desired result.

Subsequently, Ellis identified four basic forms of irrational beliefs: (1) “musturbatory” statements—believing that something or someone *should*, *ought*, or *must* be different from the way it actually does exist; (2) “awfulizing”—believing that something is *awful*, *terrible* or *horrible* when it is this way; (3) “I-can’t-stand-it-itis”—believing that one *can’t bear*, *stand*, or *tolerate* this person or thing and this person or thing should not be this way; and (4) “damnation”—believing that people have made or keep making horrible errors and because they should not act in this manner, they deserve nothing good in this life and should be forever labeled as rotten people. REBT holds that most of the irrational beliefs originate from musturbatory beliefs. Ellis has detailed 12 of the most common and frequently seen “musts” in therapy. These include all-or-nothing thinking, jumping to conclusions and negative nonsequiturs, fortune-telling, focusing on the negative, disqualifying the positive, allness and neverness, minimization, emotional reasoning, labeling and overgeneralization, personalizing, phonyism, and perfectionism.

The consequences of these and similar musturbatory statements often bring people to seek counseling. Irrational thoughts result in dysfunctional emotions and behaviors and inhibit people from living rational and effective lives. It becomes the job of the REBT therapist to work with clients and assess their ABCs of a specific belief system or systems and identify ways

in which the clients can alter those beliefs to achieve consequences that are more rational.

## Counseling Techniques

The counselor working from an REBT perspective takes an active role in identifying the client’s irrational thoughts and challenging those thoughts so that the client can differentiate between rational and irrational belief systems and choose beliefs that are more rational. This happens in the Disputing (D) component of REBT counseling. There are three aspects of this process of determining and correcting the irrational belief. The first is to debate any irrational belief. Debating can be done by asking questions such as “What evidence supports your thought?” and “In which way does it have any truth or falseness?” The primary goal of debating is to take clients’ shaky hypotheses about the world around them and actively and vigorously dispute their irrational beliefs until they are surrendered or revised. The second goal is to discriminate between musts (irrational beliefs) and preferences (rational beliefs). For example, a person has the ability to discriminate that waiting in line can be a hassle, but not a horror. Additionally, a person can argue that getting a bad grade is unfortunate, but not unbearable. The final component is to define the irrational statements being used. In the example used earlier, the irrational thought could be defined as “I always write bad papers and I am going to get a failing grade on this paper, too.” By defining the irrational thought, the client can begin to redefine the overgeneralized statement, which could become “Although I may have written a bad paper in the past, this does not mean I will always write bad papers.” Thus, in debating, discriminating, and defining the irrational thought, clients can begin the process of redirecting and restructuring their cognitive thought processes.

Once the ABCD aspects have been sufficiently covered, the individual is ready for the end result of acquiring a new Effect (E) or philosophy that replaces the old irrational belief. For example, the client might realize that, “Yes, I have written bad papers in the past and my earlier irrational attitude toward papers could be self-defeating and undesirable. I accept the fact that I am not perfect, but will work hard to produce a quality paper. If I were to again get a poor grade, however, this would be an unfortunate occurrence rather than a catastrophic event.” It should be noted that just learning the ABCs and going through D and E once is

not enough to permanently remove irrational beliefs. REBT theory states that by nature individuals are irrational beings, thus it is their natural tendency to think irrationally. It is only by actively, forcibly, repeatedly, and continually doing the ABCDEs, that rational beliefs will be maintained.

Therapy is an educational process that often includes the use of out-of-session or homework assignments. Clients are taught how to use REBT beyond therapy sessions, so that when they leave the therapist's office, they will be equipped to debate, discriminate, and define their irrational thoughts and to create their own new effective behavior or philosophy. The therapist helps to educate clients through pamphlets, books, attending lectures and workshops, and listening to tapes. One of the most important techniques used in REBT is in vivo assignments. This technique consists of homework assignments in which clients perform specific tasks outside of therapy and monitor their cognitions during the homework assignment. For example, homework assignments may consist of techniques that increase their frustration tolerance by encouraging them to remain in uncomfortable situations, antiprocrastination exercises, and skill-training exercises. Antiprocrastination exercises encourage clients to start tasks earlier rather than later, which disputes the need for comfort in the current moment. Finally, skill-training exercises provide the client with needed skills, such as assertion or increased social skills. Through these techniques, clients are able to receive positive reinforcements for their rational behavior and corrective assignments to extinguish irrational behavior. The use of REBT techniques provides the therapist with a wide array of options when counseling an individual. These techniques not only are used to help a client in the here and now, but also equip the client to address dysfunctional beliefs in the future.

### Healthy Personality

If musturbatory beliefs are the foundation of a dysfunctional person, then the absence of musturbatory beliefs constitutes a healthy person. REBT recognizes that humans have goals, wishes, desires, and wants. If these desires remain nonabsolute and do not escalate to grandiose dogmas or demands, then an individual will remain less psychologically disturbed. Since life is unpredictable and difficult, however, people will experience healthy negative emotions such as sadness, regret, disappointment, and annoyance

when their desires are not met. These negative emotions are thought to be healthy because they help people remove obstacles to attain the goal and to make constructive adjustments when their desires are not met.

In comparison to the absolutist irrational beliefs, the rational beliefs consist of rating or evaluating badness, tolerance, and acceptance. Rating or evaluating badness acknowledges that a thwarted desire is bad. The badness, however, is not rated as catastrophic or awful. Tolerance is the polar opposite of low frustration tolerance or "I-can't-stand-it-itis." Here the rational person will accept that an undesirable thing has happened, rate the event according to its badness, attempt to change the undesirable event, or accept that the event can't be changed and actively pursue other goals. Acceptance is the alternative to the irrational damnation. Through rational acceptance, a person realizes that humans are fallible creatures who will make mistakes and accepts that humans live in a complex world where there are things that are outside of their control.

There are two types of strategies in REBT: general and elegant. General REBT is synonymous with cognitive-behavioral therapy, whereas elegant REBT is unique in many different aspects. The major goal of elegant REBT is to encourage clients to make a profound philosophic change in the areas of ego disturbance and discomfort disturbance. This involves helping clients give up their irrational musturbatory processes and replace them with rational, nonabsolute thinking. Elegant REBT also helps clients pursue long-range basic goals by helping them fully accept who they are and how to tolerate unchangeable and uncomfortable life conditions (i.e., develop a healthy personality). Therapists using elegant REBT strive to help clients obtain the skills necessary to prevent irrational beliefs in the future. When it is evident that a client is not able to make a philosophical change, either with a specific behavior or in general, the therapist will often switch to using general REBT. The therapist using general REBT will apply methods to effect behaviorally based change.

## REFRAMING

---

Reframing is a technique used by counselors to shift a client's view of a particular problem, event, or person. It is based on the assumption that when clients are able to view a situation from another perspective, opportunities for finding alternative, acceptable solutions to their problems increase. The effectiveness of reframes in therapy is documented in both clinical outcomes and empirical research.

A reframe differs from an interpretation in that interpretations are associated with a basis in reality or truth. In a reframe, the therapist attempts to shift how a client views a problem as a method for moving toward change rather than replacing a faulty belief with a different, but accurate, view. The therapist's utilizing a reframe helps the client move from a linear view of a problem to a systemic and circular view. It provides a context for clients and therapists to work together toward promoting change.

### Using Reframes in Counseling

There are two core elements to the successful application of reframes in psychotherapy. Because people often associate bad intentions with inappropriate behavior, reframing that changes the manner in which a problem is perceived can change a person's

attributions and meaning of the behavior. Presenting the problem in a positive context (for example, the behavior helps the couple bond) rather than a negative one (the behavior is an indication of a lack of trust) is the first element in reframing. This is known as a positive connotation.

A second core element in reframing is moving from an individual to a systemic framework. Often when couples or families come to counseling, one person is viewed as the individual with the problem. This individual has already been targeted by the family as the one who needs to change; however, unless all family members (including the individual's partner) can view the problem from a systemic stance where members acknowledge their contributions to the maintenance of the problem, therapy will not be effective.

Movement from an individual to a systemic framework is accomplished through systemic and/or bilateral reframes. Systemic reframes are those where one statement captures the dynamics of both partners in the relationship and is positive. For example, a systemic reframe for a couple who constantly argue might be to remark how much passion and care is evident between the members of the couple, as most couples who do not care about each other do not fight. Bilateral reframes are two or more statements that reframe each individual's behavior. Both statements are commonly, but not necessarily, used in combination with a paradoxical intervention. An example of this is when a therapist congratulates one partner for resisting the other partner's attempts to move toward a more intimate relationship, as intimacy can be frightening. The other partner also is congratulated, then, for supporting his or her partner's attempts to avoid intimacy.

Reframing appears to be a simple technique, but is actually quite difficult to implement properly. Therapists should give attention to differentiating between an interpretation (a supposed statement of truth) and a reframe. Supervision should be sought when the therapist is in doubt.

## REHABILITATION COUNSELING

---

Rehabilitation counseling is a process that is designed to assist people with disabilities in accomplishing their goals and in achieving independence and full participation in all aspects of community life. Rehabilitation counseling is also a recognized counseling profession, with a long history and established professional credentialing procedures. It is variously conceptualized as a specialty within counseling, as a specialty within rehabilitation, and as a separate profession.

The historical roots of rehabilitation counseling date back to the early 1900s. During World War I, many military personnel returned home with disabilities, and rehabilitation programs were established to assist them in returning to productive civilian roles. The Soldier Rehabilitation Act (Public Law 65–178) was enacted in 1918. Simultaneously, efforts were under way in several different states to assist workers who had been injured in industrial accidents in returning to work, the roots of contemporary worker's compensation programs. Finally, the Smith-Fess Act of 1920 (Public Law 66–236) established a vocational rehabilitation program for civilians with disabilities. All of these initiatives evolved into the extensive network of government, private-nonprofit, and private-for-profit agencies and programs to assist people with disabilities. Rehabilitation counseling plays a central role within these agencies and programs, providing assessment, counseling, and coordination of rehabilitation services.

### Definitions of Rehabilitation Counseling

As is true with other professions and specialties, a variety of definitions of rehabilitation counseling have been advanced by individual scholars and practitioners and by professional organizations. An official definition of rehabilitation counseling is provided by the Commission on Rehabilitation Counselor Certification (CRCC), the national credentialing body for rehabilitation counselors, in their “scope of practice statement”:

Rehabilitation counseling is a systematic process which assists persons with physical, mental, developmental, cognitive, and emotional disabilities to achieve their personal, career, and independent living goals in the most integrated setting possible through

the application of the counseling process. The counseling process involves communication, goal setting, and beneficial growth or change through self-advocacy, psychological, vocational, social, and behavioral interventions.

This official definition emphasizes that rehabilitation counseling focuses specifically on the needs of people with all different types of disabilities; that counseling is central to the process; and that integrated settings are emphasized in the pursuit of career and independent living goals.

### Rehabilitation and Disability

#### *Rehabilitation*

Rehabilitation counseling is a part of the broader overall rehabilitation process. Medical dictionaries define rehabilitation as restoration or return to function following illness or injury. Rehabilitation is further defined as a process to facilitate independence and a return to full participation in life activities following the occurrence of disability, including employment as a core life activity. This definition is clearly encompassed within the official CRCC definition of rehabilitation counseling. When injury or illness occurs, acute care interventions are pursued to treat, manage, and stabilize the resulting medical condition. However, long-term consequences of illnesses and injuries, including disabilities, will sometimes remain after all available treatments have been pursued, and rehabilitation interventions may then be required to facilitate maximum function, full participation in life activities, and high quality of life. In addition to those disabilities that occur later in life, some occur at birth or during the early developmental years. In these cases, the same principles of assisting individuals in achieving independence, full participation, and quality of life apply. A variety of professions participate in rehabilitation programming, including physical, occupational, speech and language, and recreation therapy, rehabilitation psychology, social work, and rehabilitation counseling.

To illustrate the rehabilitation process, a spinal cord injury may occur through a variety of events, such as a motor vehicle crash, a fall, a diving accident, or a gunshot wound, resulting in paralysis below the level of the injury. An individual who sustains a spinal cord injury will often be taken to a trauma center and

will initially be treated through medical interventions to manage the acute condition and any complications that may result, and also to limit long-term adverse consequences. After the medical condition is stabilized, the individual will often be transferred to a rehabilitation unit within the hospital, where a variety of disciplines will assist the individual in recovering function and dealing with the limitations that will remain in the long term. The individual will learn new ways to perform tasks, for example, moving from place to place using a wheelchair, driving a car through the use of hand controls, and performing basic living tasks, such as eating and grooming. Many aspects of the life of the individual, as well as the lives of family and friends, will be affected. For example, the individual may no longer be able to work in the same occupation that had been a primary source of family income and personal identity. In some instances, it may be possible to help an employer identify accommodations that will make it possible for the individual to again perform the job. In other instances, the individual may need assistance in making new plans for the future. Every aspect of life may be affected, and rehabilitation professionals can participate in assisting the individual in recovering function, identifying and implementing accommodations, planning for the future, and maximizing independence and quality of life.

Rehabilitation services are provided in a variety of agencies and programs, and rehabilitation counseling is a part of the programming in many of these settings. Government programs providing rehabilitation services include agencies at the federal level (e.g., the Department of Veterans Affairs, where rehabilitation counseling is practiced in both the Veterans Benefits Administration, which coordinates disability and rehabilitation benefits, and in the Veterans Health Administration, which includes the Veterans Industries/Compensated Work Therapy Program that provides rehabilitation services to veterans with disabilities); the state level (the State-Federal Vocational Rehabilitation agencies, which exist in all states and jurisdictions in the United States, along with separate agencies for people with blindness and low vision in a number of states); and the county and city levels (e.g., local government agencies providing rehabilitation and long-term support services for people with developmental disabilities and with severe and persistent mental illness).

Many private agencies and programs also provide rehabilitation services, both nonprofit and for-profit.

Private-nonprofit programs include independent living centers (ILCs), rehabilitation facilities (e.g., Goodwill Industries), hospitals (e.g., physical medicine and rehabilitation units in university and community hospitals), disability organizations (e.g., state and local offices of the Epilepsy Foundation and United Cerebral Palsy), and a variety of community agencies providing rehabilitation and long-term support for people with disabilities (e.g., mental health, supported employment, and supported living programs). Private-for-profit programs often serve people with work or personal injuries covered by workers' compensation, automobile, and other insurance policies. These programs are sometimes a part of national and international insurance companies that provide workers' compensation or long-term disability coverage. Some are freestanding companies and private practices that may operate in one location or in many locations nationwide, and others are disability management programs that are a part of large business and industrial organizations. These programs facilitate the prevention of illness and injury and assist workers who have sustained disabilities in their attempts to return to work.

## ***Disability***

Since individuals with disabilities are the focus of the rehabilitation counseling process, it is important to define *disability*. However, different definitions of disability are advocated by different professional groups, and also by groups representing people with disabilities themselves. In addition, disability is defined by laws and government regulations, often in different and sometimes conflicting ways. These laws can have a dramatic impact on opportunities and protections provided to individuals with disabilities. For example, legal definitions of disability determine whether children are eligible for special education services in elementary and secondary schools; whether college students are eligible for accommodations, such as extended time on examinations and special services to facilitate their education; and whether adults are eligible for vocational rehabilitation services, including financial assistance with education and training in colleges and universities, technical colleges, and other types of training programs. In addition, legal definitions determine eligibility for disability benefits, such as Social Security Disability Insurance (SSDI) and Supplemental Security Income

(SSI) benefits, or for legal protections in employment and housing.

The term *disability* is sometimes used to refer to a variety of medical or related conditions (e.g., spinal cord injury, brain injury, schizophrenia, epilepsy, cerebral palsy, or diabetes), and *impairment* is sometimes used as an alternative to the term *disability* to express this meaning. In contrast, other definitions are based on the functional limitations associated with physical, cognitive, or psychiatric impairments that affect the performance of various tasks or functions (e.g., mobility, communication, self-care, self-direction, interpersonal skills, work tolerance, or work skills) or limit the fulfillment of major roles or life activities (e.g., employment and independent living). Other terms, such as *impediment* and *handicap*, are sometimes used as alternatives to disability to express this meaning. For example, for purposes of determining eligibility for SSDI or SSI benefits, disability is defined in terms of medical impairments that result in an inability to work in any “substantial and gainful activity.” In determining eligibility for services provided through the State-Federal Vocational Rehabilitation Program, disability is defined as a physical or mental impairment that results in a substantial impediment to employment. In identifying individuals who are provided legal protection under the Americans with Disabilities Act (ADA) of 1990, disability is defined as an impairment that substantially limits one or more major life activities, such as self-care, performance of manual tasks, walking, seeing, hearing, breathing, sitting, standing, lifting, reaching, learning, and/or working.

The most contemporary definitions recognize the importance of the physical, social, and cultural environment in defining disability. The environment is viewed as a primary source of barriers, stereotypes, and discrimination, which play central roles in the disabling consequences of physical, cognitive, and psychiatric impairments. Such definitions have been incorporated into ecological models of disability and rehabilitation counseling practice, which focus on interactions between individuals and their environments. Consistent with ecological models, rehabilitation counseling is not limited to traditional counseling interventions that focus on the individual. Rather, other types of interventions, such as advocacy, are also included, focusing on environmental factors contributing to disability and the interactions between the individual and environmental factors.

The variety of types of disabilities is extensive, with many different physical, cognitive, and psychiatric conditions, illnesses, and injuries. Examples include sensory disorders (e.g., blindness and low vision, deafness and hearing loss); developmental disabilities (e.g., cognitive disabilities, autism, epilepsy, brain injuries occurring during the developmental years); mental illness (e.g., schizophrenia, affective disorders, personality disorders); substance abuse and addiction disorders; injuries (e.g., spinal cord injuries, traumatic brain injuries, burns, amputations, carpal tunnel syndrome, chronic pain due to low back and other injuries); and a variety of other illnesses and conditions (e.g., stroke, cardiovascular disease, cancer, HIV/AIDS, respiratory disorders, multiple sclerosis, muscular dystrophy, rheumatoid arthritis, diabetes, chronic renal failure).

## Rehabilitation Counseling Practice

### *Guiding Principles*

Many of the guiding principles, philosophies, and values underlying the practice of rehabilitation counseling are shared by counseling in general, as well as by other helping professions. The belief in the worth and dignity of all people, including people with disabilities, is particularly important. Following from the belief in the worth of all people, rehabilitation counseling practice is dedicated to facilitating full access to opportunities for participation in all aspects of community life and to the pursuit of individually determined goals, consistent with the opportunities available to others in society. Following from the belief in the dignity of all people, rehabilitation counseling attempts to empower people with disabilities in achieving control over their own lives and the opportunities and goals that they choose to pursue. Consistent with this value is an emphasis on informed choice in rehabilitation counseling practice, viewing people with disabilities as equal collaborators in the rehabilitation counseling process and assisting them in obtaining and processing the information that they need to make their own decisions regarding services, interventions, and goals.

Also similar to counseling in general, rehabilitation counseling has a long tradition of going beyond limitations and problems to focus on the strengths of individuals with disabilities and helping them to build on those strengths in overcoming the difficulties that they

face in accomplishing their goals and living high-quality lives. In addition, the ecological perspective in rehabilitation counseling advocates a focus not only on the individual but also on environmental contexts, in assessing difficulties brought to rehabilitation counseling and in the planning of goals, services, and interventions.

Another value held in contemporary rehabilitation counseling practice, as specified in the CRCC definition of rehabilitation counseling, is the importance of pursuing “personal, career, and independent living goals in the most integrated settings possible.” Historically, career and independent living goals for people with disabilities, particularly for those with significant cognitive disabilities and severe and persistent mental illness, were often focused on segregated settings. Large numbers of people with disabilities were congregated in large work environments, such as sheltered workshops, and in large living environments, such as skilled nursing facilities, community-based residential facilities, halfway houses, and group homes. Contemporary practice emphasizes the pursuit of employment goals in regular work environments in business and industry, where individuals with disabilities will be integrated with the regular workforce, with necessary supports provided to facilitate success. Similarly, integrated living environments would be exemplified by one or two people with disabilities living in a regular community apartment building or complex, together with nondisabled people, with necessary supports provided.

### ***Rehabilitation Counseling Process***

The rehabilitation counseling process is generally consistent with the counseling process in general. The process is collaborative, with rehabilitation counselors and individuals with disabilities jointly assessing and identifying needs; establishing personal, career, and independent living goals; identifying barriers to accomplishing those goals; identifying needed services and interventions to overcome the barriers and accomplish the goals; organizing those services and interventions into a service plan; and implementing and evaluating the progress and success of the plan. Individuals with disabilities often seek rehabilitation counseling at times of change or crisis, such as the onset of a disability, changes in condition or functioning associated with disability, or times of transition (e.g., discharge from a hospital, completion of

high school and moving on to adult and community life, struggles with the demands of an education or training program, the illness or death of a caretaker, or termination from a job). At times of crisis, assistance will often be required through rehabilitation counseling in processing those changes and their implications, identifying and accessing community resources, and finding new ways to meet needs, which may precede the establishment and pursuit of personal, career, and independent living goals.

As in counseling in general, in rehabilitation counseling the emphasis is on the counseling relationship and developing a strong working alliance between rehabilitation counselors and individuals with disabilities. As is also true in counseling in general, eclectic approaches to counseling are common, with counselors drawing from a number of different counseling theories and techniques in their practice. Because of the emphasis on facilitating career, independent living, and life decisions, trait-and-factor theories and concepts are often applied. Given their emphasis on helping people build on strengths, cognitive-behavioral theories and practices can be beneficial in guiding people to develop skills for coping with difficulties and become masters of their own destinies to greater degrees.

Given the complexity of needs that is often associated with disabilities, the involvement of many different professionals, programs, and services is often required and, as a result, service coordination and case management are often critical components of the rehabilitation counseling process. In addition, given the common focus on career goals, important components of the process are often job development and placement and the facilitation of independent job-seeking efforts on the part of individuals served.

Some functions and tasks are unique or are emphasized to a greater degree in rehabilitation counseling practice than in counseling in general. Given the prominence of ecological perspectives, and the belief that problems related to disability reside in large part in the physical and social environments in which people with disabilities live and work, advocacy is emphasized. This includes both advocating for people with disabilities and assisting them in their efforts at self-advocacy. Related to advocacy, rehabilitation counselors may be called upon to consult with business, industry, and other organizations in facilitating accessibility and accommodating the needs of people with disabilities, including the identification of assistive

technology that may be used. In addition, rehabilitation counselors may be called upon to assist in legal proceedings, such as workers' compensation, personal injury, and divorce cases, to assess the impact of disability on earning potential so that appropriate compensation can be determined. Similarly, in life care planning, rehabilitation counselors may be called upon to assess the life-long service needs of individuals with disabilities, along with the costs of obtaining those services, in order to determine appropriate insurance settlements following the onset of a disability.

### **Professional Aspects of Rehabilitation Counseling**

Different points of view have long existed regarding the relation of rehabilitation counseling to other counseling and rehabilitation disciplines. Rehabilitation counseling has been conceptualized as a specialty within counseling, as a specialty within rehabilitation, and as a distinct and separate profession. The different points of view have resulted in multiple professional associations in rehabilitation counseling. Consistent with the view of rehabilitation counseling as a counseling specialty, the American Rehabilitation Counseling Association (ARCA) is a division of the American Counseling Association (ACA), along with other counseling specialties, such as employment, mental health, school, marriage and family, addiction, and offender counseling. Consistent with the view of rehabilitation counseling as a specialty within rehabilitation, the Rehabilitation Counselors and Educators Association (RCEA) is a division of the National Rehabilitation Association (NRA), along with other specialties in vocational evaluation, work adjustment, job placement, and independent living. Consistent with the view of rehabilitation counseling as a separate profession, the National Rehabilitation Counseling Association (NRCA) exists as a separate professional association, with no affiliation with a parent group, and some would consider the rehabilitation specialties represented within NRA to be specialties within rehabilitation counseling per se, focusing on particular rehabilitation counseling functions.

Rehabilitation counseling has been a pioneer in the movement toward the credentialing of practitioners, developing an accreditation mechanism for master's degree programs in rehabilitation counseling through the Council on Rehabilitation Education (CORE) and a national Certified Rehabilitation Counselor (CRC) credential through CRCC. Both mechanisms were

established in the mid-1970s, preceding by a number of years the comparable accrediting processes for general counseling through the Council for Accreditation of Counseling and Related Educational Programs (CACREP) and the National Board for Certified Counselors (NBCC).

Rehabilitation counselors are included in the licensing provisions for general counselors in many states, and a few states have separate credentials for rehabilitation counselors and related professionals, including the Licensed Rehabilitation Counselor (LRC) credential in Louisiana and New Jersey and the Qualified Rehabilitation Consultant (QRC) credential in Minnesota. Ethical standards specific to rehabilitation counseling practice were first developed and adopted by NRCA in 1972, which evolved into the current Code of Professional Ethics for Rehabilitation Counselors. The master's degree is generally considered to be the professional practice degree in rehabilitation counseling. In addition, a smaller number of universities offer programs to prepare rehabilitation counseling professionals at the doctoral degree level. Graduates of doctoral programs often enter academic positions in universities in the training of rehabilitation counselors and related professionals, in addition to positions in research, administration, supervision, and clinical practice, both within and outside of universities.

Knowledge domains specified by CRCC for inclusion in the CRC examination represent an official position regarding the competencies that are important to the practice of rehabilitation counseling. Some of the domains are shared with counseling in general, while others reflect the specialized services provided in rehabilitation settings and the unique needs of people with disabilities. Examples of more rehabilitation-specific knowledge subdomains are indicated in parentheses, following the more general domains in the following listings. Counseling is central to practice, including individual counseling, career counseling and assessment (e.g., interpretation of assessment results for rehabilitation planning, transferable work skills analysis, assistive technology), mental health counseling, and group and family counseling. Other rehabilitation counseling interventions include case and caseload management, job development and placement services (i.e., vocational implications of functional limitations associated with disabilities), and vocational consultation and employer services (i.e., employer practices that affect the employment or

return to work of individuals with disabilities, job analysis, job modification, and restructuring techniques).

Domains are also specified regarding the rehabilitation and human services systems, including rehabilitation services and resources (e.g., community resources and services for rehabilitation planning, school to work transition for students with disabilities, and Social Security programs, benefits, and disincentives affecting return to work); foundations, ethics, and professional issues (e.g., ethical standards for rehabilitation counselors and legislation affecting individuals with disabilities); and healthcare and disability systems. Finally, remaining domains relate to knowledge of disabilities and of the people typically served by rehabilitation programs, including the medical, functional, and environmental implications of disabilities and psychosocial and cultural issues.

Among the different counseling interventions, individual counseling is most commonly practiced by rehabilitation counselors but, depending on the specific settings in which rehabilitation counselors practice, group counseling may also be frequently used, along with family counseling. Career counseling is commonly practiced in many rehabilitation settings, because of the central importance of work and career for individuals with disabilities and the impact that disability can have on career direction and employment. In addition, personal issues, coping and adaptation to disability, and consideration of life decisions and plans are often the focus of rehabilitation counseling practice.

## RELATIONSHIPS WITH CLIENTS

---

The therapeutic relationship is central to counselors' work with clients. The therapeutic relationship is the association, rapport, and connection between a counselor and client. The establishment of the therapeutic relationship begins with the joining process, wherein

the counselor and client get to know each other and clarify the need and purpose for counseling. The therapeutic relationship includes such things as unconditional regard for the client, placing the needs of the client first, engaging the client in a positive and collaborative manner, understanding the client and his or her context as it pertains to the presenting problem, mutually agreeing upon treatment goals and interventions, and empowering the client. In essence, the therapeutic relationship is the interaction, connection, and process between counselor and client in efforts to bring about the desired results in therapy.

Understanding the roles that a counselor plays and that the counselor may simultaneously engage in two or more of those roles is central to understanding the concept of *dual* or *multiple relationships* (the terms are used interchangeably). Counseling professionals function in a variety of professional roles, corresponding with their education, training, and experience. These include the roles of therapist, supervisor, researcher, employer, consultant, professional association officer, or expert witness. Simultaneously, therapists are functioning in other roles related to the personal, social, and business aspects of their lives (e.g., family member, friend, religious organization member, social acquaintance, sexual partner, business partner). A multiple relationship is defined as a situation in which the therapist functions in roles associated with a professional relationship with a client and also assumes another definitive and intended role that is not inconsequential or the result of a chance encounter. The multiple relationships may be concurrent or consecutive.

The concept of boundaries is critical to the discussion and understanding of multiple relationships. A professional boundary is conceptualized as a frame or limit that demarcates what is included or excluded from the therapeutic relationship. This includes the structure and content of therapy, as well as the professional responsibilities and behaviors that appropriately help clients. Critical areas relevant to boundary issues include time, place, space, money, gifts, services, clothing, language, self-disclosure, and physical contact. Meeting clients outside of the standard location for sessions or exchanging gifts with clients are examples of potential boundary violations.

Related to the construct of boundaries is the power a person has to influence another person or events. Power has the potential to be both helpful and harmful to those involved. This is particularly the case when there is unequal power between the parties

involved and when one person has the ability to impose his or her will over others. Factors that contribute to power differences include such things as role, sex, education, and socioeconomic status. Therapists are considered to have greater power than clients in the therapeutic relationship. Therapists' professional power is derived from four sources: societal ascription, expert knowledge, client expectations, and personal power. For example, in society, therapists occupy a position of authority and respect based on the work that they do and the potential influence that they have on people. When people (e.g., clients) come to them, the expectation is that therapists are experts within the field and that they have the knowledge and ability to help clients with the problems or challenges they face. Through the licensing process, society grants professionals the right to use their knowledge and power to benefit others.

### **Rationale for Avoiding Multiple Relationships**

The inherent power differential in the therapeutic relationship raises the concern that professionals could use their power and authority to take advantage of client vulnerability and exploit clients for their personal gain. Knowledge of the potential for exploitive relationships has led to the prohibition of harmful multiple relationships by professional associations, therapists, licensing boards, ethics committees, and educators. The prohibition derives from the belief that engaging in additional relationships puts the therapeutic relationship and client at risk; that conflicting roles and boundary violations could precipitate impaired therapist judgment and exploitation of the client.

### **Boundaries**

In her book about boundary violations in professional relationships, Marilyn R. Peterson described the roles of professionals and asserted that contemporary counseling professionals function as secular shamans. Intrinsic to the shaman perspective is that shamans act in the best of interest of those they help. Building upon this perspective, Peterson elaborated that society sets counseling professionals apart, elevating them to privileged positions of power and allowing them to influence and manage people's lives. Because of this position of power and influence, it becomes even more critical that professionals respect the boundaries

of their relationship with clients and not violate the trust and confidence bestowed upon them. This responsibility requires that professionals exercise restraint and vigilance to make sure that the client's best interests come before their own. If therapists are acting in the client's best interests, then they will exercise self-restraint and avoid situations that might tempt them to abandon the needs of the client and further their own interests.

Because trust in and vulnerability to the therapist and appropriate distance between therapist and client are inherent to the therapeutic process, many experts on ethics in the counseling profession advocate for therapists maintaining strict boundaries with clients. Clear boundaries are viewed as essential in therapy, and deviation from those boundaries presents a potential threat to the therapeutic process. Those who advocate for clear boundaries also consider crossing boundaries as a potential precursor to harming the client, varying in severity from harm to exploitation or even sexual relationships with clients.

Another concept discussed in the multiple relationship literature is that of the slippery slope. The term *slippery slope* refers to the notion that failure to adhere to rigid standards will gradually lead to relationships that are exploitative and harmful to the client. This process is thought to occur when one boundary is crossed without a clear damaging result, making it easier to cross future boundaries. The acceptance of the notion of a slippery slope has led to the generally accepted caution to avoid it by avoiding boundary violations or multiple relationships with clients. In the cautionary stance of risk management, therapists are admonished to avoid certain behaviors or practices because they might be misinterpreted and questioned by licensing board, ethics committees, and courts.

### **Problematic Aspects of Multiple Relationships**

In the seminal article on what makes dual relationships so problematic, Karen S. Kitchener used role theory to explain the difficulties that arise in dual relationships when one person is involved, simultaneously or sequentially, with role categories that conflict or compete. She proposed that it is the conflicting or competing roles that become problematic and identified three specific guidelines for differentiating between dual relationships that have a high versus a low probability of leading to difficulty. The first guideline addresses

the incompatibility of the expectations associated with multiple roles (e.g., therapist and friend). When role expectations are incompatible or compete, there is often confusion about how one should behave. When these expectations are unclear or conflict, there is greater potential for feelings of frustration, confusion, and anger, which in turn could lead to actions that could be harmful. The second guideline addresses the conflicting obligations associated with the roles (protecting the client's welfare when functioning as a therapist, but reducing the client's autonomy when giving advice as a friend). The problem in confusing these roles is that there may be confusion as to the underlying intentions. The final guideline addresses the power differential and notes as that differential increases, the potential for exploitation also increases. In the face of large power differences, clients may not be able to determine if they are being harmed.

### **Unavoidable Multiple Relationships**

Another aspect of multiple relationships that makes them so problematic is that they are sometimes unavoidable. Avoiding multiple relationships is particularly difficult for therapists who practice in small, rural communities; in the military; and in definite communities with minority populations; or who are clergy and/or work in religious settings.

Unlike clinicians practicing in large urban areas where they are able to maintain anonymity, those working in rural and small communities face unique challenges. The literature related to rural and small communities reveals three characteristics that practitioners face: impact of greater distances and population scarcity, living and working in smaller communities with their formal and informal social and political units, and the multiple levels of personal and professional relationships.

For those living in rural areas, there is typically a greater physical distance between communities. As a result, members of these small communities are interdependent so that necessary services can be provided within the community. It is possible that the only choice for shopping will be a clients' store, or that the therapist's children will attend the same school or become friends with clients or clients' children. Part of the difficulty is the fact that rural therapists have limited options for referring clients to other service providers. Additionally, the longer a therapist resides in the community, the more interaction the therapist

has with community members, and the more difficult it becomes to separate professional and personal relationships. In rural communities, there is a cultural and social expectation of overlapping relationships and that “everybody knows everybody.”

For therapists who are members of small communities and/or minority groups, it may be difficult to avoid multiple relationships. Clients frequently choose therapists because they are a part of a shared community and are expected to be more sensitive to the clients’ issues. Small, shared communities include not only therapists from minority ethnic backgrounds but also gay and lesbian therapists. The ethical dilemma of being known and setting personal boundaries within these small communities can be especially complex and daunting for these therapists. All therapists, and particularly those within small communities, need to make sure that their social, emotional, and sexual needs are met through relationships with friends, colleagues, family, partners, or others and not through relationships with clients. It is important that therapists prepare for these unavoidable multiple relationships by increasing their awareness of their own needs, establishing their own guideline or model for managing unavoidable multiple relationships, having competent colleagues with whom to consult, and having outlets for personal fulfillment and satisfaction outside of the therapeutic setting. It is also essential that therapists who navigate unavoidable multiple relationships have frank and clear discussions with clients about how they will manage the complexities of the multiple relationships, including potential conflicts and how those conflicts will be addressed and resolved.

### **Sexual Relationships With Clients and Their Impact**

Sexual relationships with clients are the most extreme form of multiple relationships. The American Psychological Association (APA) Code of Ethics and Standards of Practice clearly prohibits therapists from having sexual relationships with their current clients. Relationships with former clients (after a 2-year time period of no therapeutic contact) are not considered unethical, but are strongly discouraged. As a result of the ethical and legal prohibitions, therapists’ sexual involvement with current clients is rare. Depending on the survey, the frequency of therapist-reported sexual contact between therapist and client ranges from 0% to 3% for female therapists and from 3.8% to

13.7% for male therapists. There is little information pertaining to client reports of the frequency of sexual contact between therapist and client. The literature has shown that a sexual relationship between therapist and client is harmful to the client. This harm ranges from affecting the client’s emotional, social, and sexual adjustment, to negative feelings about the experience, a negative impact on his or her personality, and a negative impact on the client’s sexual relationship with his or her primary partner.

In describing the negative effects of therapist–client sexual involvement, Kenneth S. Pope reported that it commonly results in a distinct clinical syndrome, which he termed the *therapist-patient sex syndrome*. This syndrome has symptoms similar to those seen in sexual abuse, child abuse, posttraumatic stress disorder, battered spouse syndrome, and rape response syndrome. Just like in these other syndromes, in therapist-patient sex syndrome the appearance of adverse effects may be delayed. The 10 aspects identified as characteristic of this syndrome are ambivalence; feelings of guilt; a sense of emptiness and isolation; sexual confusion; impaired ability to trust; identity, boundary, and role confusion; emotional lability; suppressed rage; increased suicidal risk; and cognitive dysfunction. These adverse effects, and the severity of most of them, attest to the harm clients experience when their therapists are sexually involved with them.

### **Argument for Nonsexual Multiple Relationships**

In addition to the fact that some multiple relationships are unavoidable, some therapists argue that the avoidance of nonsexual multiple relationships is, in fact, detrimental to clinical work with clients. Those in favor of multiple relationships emphasize the distinction between a boundary violation and a boundary crossing. A *boundary violation* is a departure from clinical practice that places the client or therapeutic process at risk. Boundary violations refer to actions on the part of the therapist that are harmful, exploitative, and in direct conflict with the preservation of the clients’ dignity and the integrity of the therapeutic process. Examples of boundary violations are sexual and financial exploitation of the clients. *Boundary crossing* is a nonpejorative term that indicates a departure from traditional therapeutic settings or constraints. Examples of boundary crossings are making home visits to a bedridden sick client; taking a plane

ride with a client who has a fear of flying; attending a client's wedding, child's bar mitzvah, or other functions; or conducting therapy while walking on a trail with a person who requests it and seems to benefit from it. Not all boundary crossings are harmful, and therefore not all are violations. In addition to encouraging the distinction between boundary violations and boundary crossings, proponents of multiple relationships argue that rigid boundaries are contrary to being clinically helpful to clients.

The rationale for engaging in benign boundary crossing is based on research on the importance of rapport and warmth to the effectiveness of therapy. Proponents of this position describe boundary crossings as being a means for increasing familiarity, understanding, and connection and thereby increasing the likelihood of success for the clinical work. They further argue that the maintenance of rigid boundaries between therapists and patients in many small, close-knit communities is unrealistic and impossible. They cite the social norms within these communities of flexible and permeable boundaries and mutuality as requiring less rigid boundaries between professionals and their clients and argue that imposing such rigid boundaries on these communities is countertherapeutic.

Proponents of this view do not dismiss the importance of the power differential in the relationship, but suggest that power has become interchangeably associated with exploitation and harm in the ethics literature. They assert that it is not the power differential or multiple relationship that is problematic, but rather the therapists' propensity to abuse their power for selfish gain. Supporters of multiple relationships also argue that using the power differential as a rationale to avoid multiple relationships is insulting and dismissive of the clients' power and ability to navigate relationships and make decisions for themselves.

### **Guidelines for Decision Making With Multiple Relationships**

Sexual relationships with clients are clearly defined as unethical and harmful to clients. Although there is little research regarding the effects or benefits of nonsexual multiple relationships with clients, the generally accepted stance in the field is that therapists should exercise caution in developing additional relationships with clients. While professional codes of ethics provide general guidelines, they do not provide clear and specific direction for every situation that may arise for

therapists. It is up to the individual therapists to assess and evaluate clinical situations and choose behavior that they believe is the most ethical, legal, and beneficial to the client. This is part of the therapists' professional responsibility. To this end, it is important that therapists either adopt an existing ethical decision-making model or formulate or adapt one of their own.

Building upon existing ethical decision-making models and K.S. Kitchener's guidelines regarding role theory and relationships, Michael C. Gottlieb developed a model for avoiding exploitive multiple relationships. Gottlieb's model is based on three critical dimensions of the ethical decision-making process: power, duration of the relationship, and clarity of termination. *Power* refers to the amount of power the therapist has in relation to the client. *Duration of the relationship* has to do with the time involved and is related to power in that power increases over time. Power is low when the relationship is brief, but increases as relationship continues. *Clarity of termination* refers to the client's perspective of how long the professional relationship will continue. Gottlieb encouraged therapists to evaluate each of these dimensions from the client's perspective, determine the risk of being perceived as exploitive, and then determine if they want to proceed with the additional relationship. If a therapist does choose to pursue another relationship in addition to the therapeutic relationship, the therapist should consult with a colleague and discuss it thoroughly with the client. The therapist should review the entire ethical decision-making process and the potential risks and/or adverse consequences so that, if the client chooses to engage in the additional relationship, it is done with informed consent.

### **The Responsibility of the Therapist**

Therapists are expected to be responsible professionals and monitor themselves when it comes to multiple relationships. They must be aware of themselves (integrity, competence) and keep any of their personal issues or self-serving behaviors in check. They do this by making sure that they are appropriately connected to significant others, family, friends, and colleagues, and that their needs are being met through these interactions rather than through relationships with clients. When therapists find themselves vulnerable and at risk, they should seek appropriate support and guidance through consultation with colleagues, supervision, or personal therapy. This is critical to avoiding

multiple relationships, but even more important in those instances when a therapist is already involved in an overlapping or multiple relationship. It is also essential that the therapist is self-aware so as to keep self-interest in check and to keep clients' interests at the forefront. This self-monitoring is also critical in the area of boundaries in order to avoid boundary crossings that continue down the slippery slope to boundary violations. By engaging in careful self-awareness, therapists recognize multiple relationship issues and ethical dilemmas, use ethical decision-making models to plan for and facilitate ethical practice, and behave in ways that are in the best interest of clients.

---

## RESILIENCE

---

Resilience, or resiliency, is the ability to survive, and thrive from, stressful experiences while building up protective skills to manage future hardship. Psychological resilience involves *cognitive, emotional, social, and physical* skills. Researchers have identified many factors that facilitate resilience and healthy adaptation to negative events and threats. For example, strong interpersonal social skills foster subsequent positive and prosocial behavior and relationships. Strong interpersonal skills help buffer stress and encourage support from others. Emotional intelligence (EI) is another trait or skill that buffers stressors and builds resilience. Emotional intelligence skills include self-awareness, other-awareness, modulation of emotions, identifying emotions in others, and responding appropriately and effectively in a positive manner. Cognitive skills that build resiliency include learning how to identify and dispute negative thinking, using critical thinking strategies in order to make more effective and accurate appraisals of negative events, thinking optimistically and having a sense of control and management over hardship, and reframing thoughts or ideas into proactive ones. In the physical realm,

demonstrating prosocial behavior that encourages and facilitates personal development, through giving, sharing, and helping others, builds resilience.

Although there has been some disagreement in the definitions of resilience across cultures, researchers agree that certain skills and strengths acquired in childhood help build resilience. Strong social skills and relationships in youth help buffer stress. Those who are involved in extracurricular activities like sports or music seem to have strong interpersonal skills that boost confidence and maturity. Involvement in activities also increases contact with others that facilitates solid support systems. The ability to interact and have rewarding relationships with peers and adults using effective communication and demonstrating appropriate personal boundaries builds self-esteem. The ability to problem solve is an active demonstration of resiliency. The ability to manage one's own emotions and assess the emotional response of others is paramount in developing and maintaining resilience.

Environmental factors related to resilience include higher socioeconomic level, levels where caregivers are not overly stressed and focused on financial security. Stability in schools and an educational environment where creativity and talent are nurtured and respected are additional factors in cultivating resiliency.

Other factors that foster resiliency are stable healthy families that encourage healthy developmental outcomes in children and consistent parenting that promotes autonomy, cooperation, independence, competence, and self-regulation with appropriate boundaries. Temperament is also related to resilience. Children are born with certain traits that endure over time and are modified and shaped by environment. A "good" fit between parents and children is crucial to bonding and subsequent development.

Resilience develops over time and is not considered a trait. Research on resilience has included terms like *adaptive coping*, *emotional coping*, *psychological resilience*, *learned optimism*, *hardiness*, *thriving*, and *flourishing*. These terms are used somewhat interchangeably.

### History of the Study of Resilience

Norman Garmezy first coined the term *resiliency* when he began studying adults with schizophrenia in the 1940s. His work led him to discover factors that buffer individuals from psychopathology. In the

1970s, he focused on identifying risk factors and developing resiliency strategies. The heightened interest in resilience research has occurred as a result of more at-risk youth being identified for serious lifelong problems, and the concomitant desire to identify factors that would reduce or prevent the occurrence of these problems. A widely used assessment for identifying resilience, The Denver Developmental Screening Test, was developed by William K. Frankenburg in the 1960s. Scientists continue to discover strengths and factors leading to resilience.

When scientists Emmy Werner, Michael Rutter, and Garmezy discovered that more than 30% of those living in at-risk conditions were surviving and thriving, despite severe hardship, they committed to discovering what strengths provided such protection. Circumstances associated with an at-risk designation include, but are not limited to, poverty, despair, lower socioeconomic levels, instability in schools, poor interpersonal skills, pessimism, limited access to health care, poor critical thinking skills, poor mental and/or physical health, antisocial behavior, unstable families, no belief in God or a higher power, inconsistent parenting, and a lack of warmth and love.

### Development of Resilience

Scientists across disciplines have begun to recognize many common factors that are associated with psychological and emotional resilience. Numerous longitudinal studies have assessed what factors contributed to resilience over time. One category of factors includes infant bonding and attachment style. Attachment styles set the stage for values, attitudes, and basic skills that are integral to the development of resilience. Attachment styles begin to develop in early childhood and are refined through adulthood. Therefore, scientists have concluded that parents are a major influence on the development of resilience, through modeling; support; teaching self-reliance and interpersonal skills; setting appropriate limits; showing love and facilitating healthy attachment and bonding; and demonstrating and teaching moral values, problem-solving skills, and self-control. An environment where emotional warmth is demonstrated is integral to the development of resilience.

Traits, like temperament, and environmental characteristics play a role as well, but seem to be lesser influences in the development of resilience. In addition to the factors related to the development of resilience in

children, researchers are identifying resilient qualities in middle-age and older adults. Adults who experience crises fare best when they are socially integrated and able to share their feelings with friends and peers, use their strengths to cope with daily activities, and seek professional help when needed. Those who maintain resilience take action when crises occur, while seeing adversity as part of life. They feel competent to solve problems, nurture and care for themselves to stay healthy, manage their emotions, and have a realistic sense of hardship. Resilient individuals find meaning in adversity; this meaning-making tends to facilitate personal growth and a renewed sense of and gratitude for life. Adults who can look to the future and not focus on the past seem to fare best.

With the psychosocial stressors in the last decade, including the natural disasters around the world, economic downturn, and international strife, researchers have been especially interested in promoting factors that help individuals thrive and flourish, rather than just survive. Resilience is being tested and studied across all domains and cultures. Researchers have learned that resilience is developed over time by experiencing conditions of environmental protective factors and/or developing skills, cognitive awareness, and strategies that facilitate resilience. In childhood, skills and strategies for coping are learned, and over time, developed, enhanced, and internalized. In adulthood, resilience factors are embedded in the personality and become part of the constellation of competencies individuals use to cope with life's adversities.

### **Clinical Applications of Teaching Resilience**

The field of psychology is moving toward a prevention model, including education that teaches what qualities, skills, and strategies promote and maintain resilience and subsequent well-being. Researchers have identified many factors that promote resilience, and educational institutions are beginning to institute resilience-enhancing programs to students. School settings are a natural environment for cultivating qualities related to resilience. Children spend 7 to 10 hours per day in school, and thus, have many opportunities in that setting to build strategies and skills for success. Protective factors that lead to resilience and coping can be taught from kindergarten through high school. Research demonstrates that a framework for developing resilience should include helping children avoid risk exposure, minimizing

consequences from risk exposure, fostering self-reliance and esteem by teaching children how to reframe negative thinking, and providing opportunities for personal growth. Policy in schools must meet the demands of a diverse population and help children find their strengths instead of trying to manage negative behavior. The fostering of factors associated with resiliency must be part of the learning environment. Schools are vital to helping youth to be resilient.

Parents and communities have roles to play in this educational process. Parents, teachers, and caregivers can promote solid emotional, cognitive, behavioral, and social skills in youth. The shift from identifying risk factors to identifying resilience factors is the focus of contemporary research. Chris B. Rush, president of the Resiliency Institute, created a model for resiliency, *The Seven Keys to Resiliency*, which helps teach and foster skills that help youth develop into healthy and productive citizens. The American Psychological Association (APA) has adopted and embraced his model, and Martin Seligman, past president of the APA, has been conducting research on resiliency factors since the 1960s. Seligman and colleagues conduct the Penn Resiliency Program (PRP) to help children build strong cognitive skills for coping with adversity.

Sybil Wolin and Steve Wolin are also primary researchers in resiliency studies. The Search Institute has been at the forefront of research for more than 20 years. There are many educational programs around the world teaching resiliency skills and strategies, with more in development.

The research demonstrates that resiliency skills are best learned and internalized during youth, however, current researchers are studying how adults can learn to change their thinking and manage their emotions and behavior to develop resilience. Psychologists and other trained mental health professionals have the ability to teach adults how to recognize and capitalize on their strengths rather than just addressing their weaknesses. Since all people have the capacity for resilience, it is reasonable that clinicians can help those who feel a sense of hopelessness regarding their situations to find and develop their strengths. In her pioneering work over the last 30 years, Emmy Werner has demonstrated how Native Hawaiians have overcome adversity and thrived, despite overwhelming odds. The results of many long-term studies are positive for those who grow up in at-risk environments.

Schools, parents, and communities at large can play a big part in the development of resilience. The

community must commit to working together with parents, educators, and other institutions to cultivate an attitude toward identifying and fostering strengths that lead to the development of resilience. Since resilience is developed over time, optimal conditions of environmental protective factors, cognitive awareness, and strategies that facilitate resilience can set the stage for optimal development. Researchers will continue to identify what factors constitute resilience. Parents, communities, and schools are starting to work together in helping children thrive, not merely survive, when adversity strikes. Although there is no one factor that determines who will develop resilience, the research clearly demonstrates that all human beings have the potential to develop their strengths.

## ROGERS, CARL R. (1902–1987)

---

Carl Ransom Rogers developed a robust humanistic psychological theory and therapy that established him as a preeminent exponent of and eloquent spokesperson for psychology's third force (humanism). In doing so he transformed the ways in which the counseling process is conceptualized and conducted. He embarked upon an ambitious experimental campaign to subject his theoretical and therapeutic ideas to empirical scrutiny and testing. He also sought to apply his humanistic philosophy to other substantive areas of inquiry (e.g., education and international relations). Most contemporary counseling psychologists acknowledge the central importance of the core conditions in therapeutic change. Many of Rogers's ideas about the counseling process, once considered revolutionary, now influence or have been integrated into today's practice of counseling throughout the world. His seminal ideas have vastly enriched and expanded our vision about personality functioning and change and will continue to fruitfully influence and affect counselors and clients for countless generations to come.

### Education and Career

Rogers obtained his B.A. in 1924 from the University of Wisconsin, and his M.A. in 1928 and Ph.D. in 1931 from Columbia University. He served as a psychologist at the Rochester Guidance Center (1928–1939), professor of psychology at the Ohio State University (1940–1945), professor of psychology and Executive Secretary of the Counseling Center of the University of Chicago (1945–1957), and professor of psychology

and psychiatry at the University of Wisconsin (1957–1963). He concluded his career with appointments at the Western Behavioral Sciences Institute from 1964 to 1968 and the Center for the Studies of the Person from 1968 to 1987. He received a Distinguished Scientific Award in 1956 and Distinguished Professional Contribution Award in 1972 from the American Psychological Association.

### Contribution

Rogers's most enduring contribution to counseling was his *client-centered* (also referred to as *person-centered*) approach. To best understand his system, three areas require attention: (1) the client-centered view of disturbance, (2) the therapeutic conditions of personality change, and (3) the process of therapeutic change.

#### ***The Client-Centered View of Disturbance***

Clients who come for counseling experience some type of disequilibrium. This is the product of conflict, tension, and distress, which result from dishonesty with self. At its most fundamental level, Rogers viewed disturbance as originating in an individual's losing trust in his or her "self." As this occurs, individuals begin to distort, deny, or inauthenticate their own experience of the world, and over time to separate increasingly from that fully, freshly felt experiencing of self and the world. Rogers used the term *incongruence* to capture this idea of the discrepancy between one's self and one's experience. As incongruities emerge, increase further in magnitude, and become incorporated into everyday functioning, the individual operates more on a basis of "what I should be" or "who I must be" than on a basis of "who I am."

Rogers's belief in humanity was eminently positive, optimistic, and proactive. He believed that each person possesses an inherent tendency to fully develop his or her capacities, a process Rogers termed *self-actualization*. Though life experiences can derail this tendency, this "great upward striving" still calls to us. Clients may express this in myriad ways: "Something doesn't feel right," "I don't believe that I'm being true to myself," "I really think I'm selling myself short," "I don't like it when I do that." Clients experience that something is wrong (e.g., conflict, tension, or distress), they sense that this involves a compromise of self (e.g., incongruity, discrepancy, or dishonesty), and they wish for a better adjustment

(actualization). The antidote for these disturbances lies in reconnecting clients with their authentic selves; reestablishing the process of their listening to, valuing, and trusting their innermost selves; and setting them on the path to becoming fully functioning individuals.

#### ***The Therapeutic Conditions of Personality Change***

For Rogers, the key question in the therapeutic relationship was: How can the counselor provide a relationship that the client can use for personal growth? That question expressed Rogers's heartfelt conviction that the counselor provides a helping, facilitative relationship that has the potential to liberate clients from their incongruous, unactualizing way of being. When that helping, facilitative relationship is provided, clients will *use* it to help themselves grow. Clients are capable of personal growth in a counseling relationship characterized by three core conditions: empathic understanding, unconditional positive regard, and genuineness.

*Empathic understanding* is often defined by the phrase "walk a mile in my shoes." Rogers advocated that counselors (metaphorically) crawl into the skin of their clients, to see as they see, to think as they think, and to feel as they feel. By profoundly understanding their clients, communicating that understanding, and facilitating further and deeper exploration, counselors open the way for clients to begin listening to and understanding themselves. For Rogers, being empathic was the core facilitative condition that freed clients to use the counseling relationship to grow.

*Unconditional positive regard* (also referred to as *nonpossessive warmth*, *respect*, *liking*, *acceptance*, and *prizing*) is an appreciation of clients for who they are. It also involves a positive respect for and acceptance of the client's immediate experiencing. In the words of Thomas Harris's popular 1969 book, *I'm OK—You're OK*, positive regard involves genuinely feeling and communicating to clients that they are "OK."

*Genuineness* (also referred to as *realness*, *congruence*, and *transparency*) entails honestly being yourself in the counseling relationship. The counselor puts up no front or façade. Genuineness involves honesty, expressed with sensitivity, compassion, and appropriateness. Although genuineness is difficult to define concretely, when present in a counseling interview, its

salience is incontrovertible, its presence palpable, and its power miraculous.

### ***The Process of Therapeutic Change***

Rogers's conception of the therapeutic change process has been likened to peeling an onion—taking off one layer at a time. The therapeutic change process cannot be rushed. Therapeutic change takes time. Each client's needs must be considered and respected, and a program of change must be charted accordingly. Clients should be allowed to proceed at the pace that promotes optimal growth and learning. Generally, personal growth involves the development of the self from more general and undifferentiated to more specific and differentiated; from blocked to unblocked; from less open to more open; from more distant to more immediate; from less responsible to more responsible; and from compromised function to full function.

Rogers conceived of the therapeutic process as involving seven stages. Clients in the first stage refuse to acknowledge that a problem exists and are unwilling to talk about anything other than external generalities. This is typical of involuntary clients. In stage two, clients perceive problems to be of external origin and fail to recognize their own personal contribution. A limited acceptance of their feelings and some freer self-expression occurs in stage three. In the next stage clients become more present focused, further accept and own their feelings, and begin to evidence some self-responsibility; self-acceptance and self-responsibility are further enhanced in stage five. The clients' internal communications are clear, their perceptions of their experiences are sharp, and their focus is present oriented in the penultimate stage. The final stage of counseling is characterized by the highest levels of immediacy and openness to experience, and by the emergence of self-acceptance and self-responsibility.

## **RYFF, CAROL D. (1950– )**

---

Carol D. Ryff is Director of the Institute on Aging and Professor of Psychology at the University of Wisconsin-Madison. She received her doctoral degree in 1978 from The Pennsylvania State University in Human Development and is a fellow of the American Psychological Association's Adult Development and Aging division (APA Division 20) and the Gerontological Society of America. Her research centers on the study of psychological well-being, an area in which she has developed multidimensional assessment scales that have been translated to more than 25 different languages and are used in research across diverse scientific fields. Investigations by Ryff and her colleagues have addressed how psychological well-being varies by age, gender, socioeconomic status, ethnic/minority status, and cultural context as well as by the experiences, challenges, and transitions individuals confront as they age. Whether psychological well-being is protective of good physical health is also one of Ryff's major interests and the source of her ongoing longitudinal investigations linking

positive psychosocial factors to a wide array of biomarkers (neuroendocrine, immune, cardiovascular) as well as to neural circuitry. A guiding theme in much of this inquiry is human resilience—that is, how some individuals are able to maintain, or regain, their well-being in the face of significant life challenge and what neurobiological, psychological, and social factors underlie this capacity.

Ryff's model of psychological well-being, encompassing six dimensions, has been instrumental in developing a well-being enhancing psychotherapeutic strategy, called *well-being therapy*. This therapeutic approach has been validated in several randomized controlled studies. Impairments in environmental mastery, autonomy, personal growth, interpersonal relationships, goal in life, and self-acceptance, the six dimensions of well-being, are frequently observed in clinical practice. Another important area of application is concerned with the process of recovery. Ryff's work has yielded seminal implication for counseling and clinical psychology, psychiatry, and psychosomatic medicine all over the world.

Ryff has written more than 120 publications in the research areas described above, and she currently directs the Midlife in the United States (MIDUS) longitudinal study, which is based on a large national

sample of Americans, including twins. Funded by a \$26 million grant from the National Institute on Aging, MIDUS II has become a major forum for studying health in aging as an integrated biopsychosocial process.

## SCHIZOPHRENIA, ADULT

---

*Schizophrenia*, derived from the Greek for “severed mind,” refers to a mental disorder characterized by the fragmentation of mental functioning and a split between thinking and feeling. This entry discusses the definitions of the concept; the epidemiology and prevalence; and the course, causes, and functional assessment of schizophrenia. Then, this entry addresses rehabilitation, evidence-based practice, policy issues, and recovery.

### Definitions

The origin of the concept of “schizophrenia” is usually attributed to the German psychiatrist Emil Kraepelin. Kraepelin first used the term *dementia praecox*, or “premature dementia,” to distinguish it from other psychotic illnesses. In the early 20th century, the Swiss psychiatrist, Eugen Bleuler, argued that the term *dementia* is misleading because dementia suggests an irreversible progressive brain disease. Bleuler stated that the most salient characteristic of the disorder is not its onset nor its course, but the particular nature of its expression in cognitive functioning. He proposed the term *schizophrenia* to suggest the fragmentation of mental functioning and a split between thinking and feeling. Bleuler also argued that there is extensive variability among individuals who had obtained this label, suggesting that there is a group of similar but distinct disorders. He made the new name plural, *the schizophrenias*. Although the term *schizophrenia* is used in contemporary

diagnostic systems, the diagnostic criteria and subtypes found in the *Diagnostic and Statistical Manual (DSM)* are largely those of Kraepelin.

*DSM* diagnosis of schizophrenia requires the presence of at least two types of psychotic symptoms, including hallucinations, delusions, irregular affect, and confusion or disorientation. Delusions alone are sufficient if they are “bizarre” (i.e., they could not possibly be true, as when a person believes he or she is dead). Symptoms must be present for at least 6 months, unless suppressed by treatment, and must be accompanied by impairment in personal and social functioning. The diagnosis may be elaborated by the assignment of subtypes, based on the specific quality of the symptoms and the course of the disorder.

Historically, the concept of schizophrenia, and of psychiatric diagnosis in general, has been criticized as not being grounded in theory. Furthermore, in contrast with medical diagnoses, psychiatric diagnoses do not identify the cause of the illness. Typically, two opinions in the contemporary psychiatry and psychopathology communities emerge when describing schizophrenia. The first is a traditional view that schizophrenia is a unitary disease much like Kraepelin originally described. The second view is that schizophrenia is a generic category for a variety of specific disorders that have little in common other than periods of psychosis. This ambiguity is reflected in the existence of a related diagnosis, *schizoaffective disorder*, in which characteristics of schizophrenia co-occur with characteristics of affective disorders, primarily bipolar disorder or depression. Even when diagnosed rigorously with the criteria provided by the *DSM*, people receiving the diagnosis of schizophrenia

comprise a very heterogeneous group with respect to age of onset, symptoms and other behavioral expressions of illness, degree of functional disability and other characteristics. There is no clinical picture that is unique to or always present in “schizophrenia.”

For these reasons, the term *schizophrenia* has limited utility in clinical treatment, social policy, or mental health administration. This has stimulated widespread use of the more inclusive term *serious mental illness* (SMI), which captures schizophrenia’s essential features, including a chronic course and severe functional disability.

Symptoms that are associated with schizophrenia can be separated into positive, negative, and disorganized symptoms. Sensory experiences, thoughts, and behaviors that are present but not typically found in people without the illness (e.g., hallucinations, delusions, and bizarre behavior) are called positive symptoms. Negative symptoms are so named because they refer to an absence or reduction of thoughts, feelings, and behaviors (e.g., reductions in communication, inability to feel pleasure (anhedonia), psychomotor retardation, apathy, and blunted affect). Negative symptoms are sometimes subdivided into primary and secondary symptoms. Primary negative symptoms are a direct expression of the disorder, while secondary symptoms are indirect consequences, such as depression consequent to loss of functioning, or side effects of medication (e.g., sedation). Finally, disorganized symptoms refer to a fragmentation of experience or behavior (e.g., disorientation, incoherent speech, purposeless motor activity). Although the most salient characteristics of schizophrenia tend to be positive or disorganized symptoms, negative symptoms account for a significant degree of morbidity associated with the disorder. Similarly, one of the most important insights about schizophrenia in recent decades has been that the disabilities associated with schizophrenia stem at least as much from the inability to perform activities of routine daily living as from symptoms.

### Epidemiology and Prevalence

Schizophrenia occurs in 1% to 1.5% of the population. This rate is approximately the same across cultures. The meaning of this estimate is questionable, however, due to its reliance on the traditional diagnostic system. About 3% of the general population meet the more inclusive criteria for serious mental illness

(SMI). The economic burden of SMI (e.g., cost of treatment, supportive social services, loss of productivity) is comparable to that of heart disease or cancer.

### Course

The onset of schizophrenia typically occurs around adolescence. While the majority of individuals undergo a prodromal phase that involves a slow and gradual development of symptoms, onset can also be abrupt. Many factors can influence the onset and course of the disorder, including stress, genetics, environmental factors, gender, and culture. The course is usually episodic, meaning there are periods of more pronounced psychosis interspersed with periods of relatively intact functioning. However, people who meet diagnostic criteria are highly heterogeneous with respect to the frequency, duration, and severity of episodes. In some individuals, the episodes are so frequent, severe, and/or prolonged that the psychosis appears to be continuous.

Contrary to the common belief that persons afflicted with the disorder are doomed to interminable incapacity, many actually recover. Bleuler’s opposition to Kraepelin’s view of dementia praecox was based in part on his observation that approximately one third of people diagnosed with schizophrenia recover. Systematic research suggests that people recover at even higher rates, with up to two thirds recovering or significantly improving.

### Causes

There is no single pathogen in the origins of schizophrenia. An array of factors interacts to produce the wide variability associated with the disorder. Environmental factors, especially stress, are thought to interact with a diversity of genetic, neuroanatomical, neurophysiological, neuropsychological, and behavioral *vulnerabilities* to produce the disorder. These interactions are understood to exert their influence over the span of childhood and adolescent development.

Genetic factors appear to play an important role; having a first-degree relative with schizophrenia increases a child’s risk of eventually being diagnosed with the disorder from 1.5% to approximately 10%. An identical twin with the diagnosis increases the risk for the other twin to about 50%. Pregnancy complications, abnormal fetal development, and/or birth complications are also related to an increased

rate in developing schizophrenia. Theories about the mechanisms of genetic causes range from vulnerability to prenatal viral infection to abnormal distribution of specific neurotransmitter receptors.

Many studies have found structural abnormalities in the frontal lobes, temporal lobes, and basal ganglia. These studies support the theory that schizophrenia involves a widespread disturbance in cognitive coordination and its underlying neural basis. These findings may account for the wide range of cognitive deficits associated with schizophrenia. Neurodevelopmental studies reveal common neuromotor abnormalities in infancy and early childhood in individuals who develop schizophrenia in adolescence or adulthood.

Environmental factors such as poor nutrition, exposure to chemicals, viral disease, trauma, and psychosocial stressors may also result in an increased risk for the disorder. Possible links between environmental events and structural brain abnormalities include *developmental neurodysplasia* and *cortisol*. Neurodysplasia is a relatively subtle disruption of brain development. The second trimester of gestation appears to be an especially vulnerable time for neurodysplasia to be induced through genetic abnormalities, viral infection, and toxic levels of cortisol or physical injury. Cortisol is a hormone secreted when a person is under stress. High levels of cortisol may produce neural cell death in brain areas associated with schizophrenia. Additionally, high cortisol levels in a pregnant woman may affect brain development in the fetus.

At the neurophysiological level, schizophrenia is generally understood as an episodic dysregulation of brain activity, possibly as a consequence of neuroanatomical abnormalities. The neurophysiological dysregulation is primarily mediated by the neurotransmitter dopamine. Pharmacological agents used to treat psychosis all affect the dopamine system, but there are intricate interactions between dopamine and other neurotransmitter systems, especially those mediated by serotonin. Newer pharmacological agents tend to have multiple actions across neurotransmitter systems.

Psychosocial influences can serve as environmental vulnerabilities that may exacerbate the disorder and further decrease functioning (e.g., family difficulties, poor interpersonal relationships, lack of social supports). Progression of the disorder can also be influenced by institutionalization and assumption of a “mental patient” social role. This highly dynamic accumulation

of environmental and behavioral vulnerabilities, interacting with biological vulnerabilities, determines the lifelong course of the disorder.

## Functional Assessment

Functional assessment is an individualized approach used in the assessment and treatment of individuals with SMI. Since the 1960s, functional assessment has become a very important clinical tool. Strengths and liabilities are evaluated on a continuum that includes neurobiological, cognitive, behavioral, and social-environmental levels of functioning. The most molecular levels of functioning include the impact of neurophysiological abnormalities. The intermediate levels include cognitive abilities (e.g., problem solving, self-monitoring, ability to make social inferences). The most molar levels of functioning extend to the person’s environment, and include family functioning, cultural attitudes about mental illness, and implications of public policy on service provision for individuals and families affected by SMI. The functional approach recognizes human beings as complex integrated systems, while affording a comprehensive picture of a client’s level of functioning, regardless of diagnosis. Most importantly, functional assessment informs *case formulation*, a comprehensive approach to understanding and treating the whole person.

## Psychiatric Rehabilitation

Psychiatric rehabilitation is an integrated approach that combines functional assessment, psychosocial interventions, and biomedical treatment. Over the past three decades, psychiatric rehabilitation has gradually gained favor over “medical model” approaches limited to drug treatment and social support. Psychiatric rehabilitation typically combines multiple assessments and interventions (e.g., rehabilitation counseling, social skills training, wellness or illness management, cognitive therapy). The person undergoing treatment is a key collaborator in this process. Rehabilitation focuses on the reduction of disability while promoting more effective adaptation to the individual’s environment by using specific interventions to improve coping and behavioral abilities. This approach assumes that community adaptation consists of three factors: the characteristics of the individual, the community’s requirements for adequate functioning, and the supportiveness of the environment. Each

of these three areas is a focus of assessment and treatment. Rehabilitation composed of comprehensive services combined with assessment and interventions that are individually tailored to clients' needs has consistently resulted in a significant improvement in functioning. Psychiatric rehabilitation provides a promising approach to helping people in institutional settings achieve the abilities necessary to live in the community.

### Evidence-Based Practice

Recently, the concept of evidence-based practice (EBP) has become a major focus of attention in health care, within and outside of mental health care. Treatment of schizophrenia is no exception. However, definitions of what constitutes "evidence-based practice" range from specific treatments tested in randomized controlled trials to broader combinations of empirical evidence, clinician experience, and systematic consideration of client values and desires. EBP principles can be straightforwardly applied to the specific modalities of psychiatric rehabilitation (e.g., pharmacotherapy, social skills training, and supported employment). It is less clear how evidence-based practice can be applied to the holistic, individualized approach of psychiatric rehabilitation. There is a pervasive tendency for mental health policy to adopt a "one size fits all" presumption about service needs despite the fact that people with SMI comprise a heterogeneous group with vastly diverse individual needs. Similarly, as recovery progresses, it is expected that different types of services will be optimal at different times throughout a person's life. The near future will probably see extensive adaptation of evidence-based practice principles to the complexities of SMI and psychiatric rehabilitation.

### Contemporary Policy Issues

Treatment and other services for SMI have undergone major structural changes over the past half century. Deinstitutionalization in the 1960s resulted in a change from an institution-based to a community-based mental health system. Unfortunately, many gaps and inconsistencies occurred in the community mental health system. Only the people who had a sufficient level of functioning and skill were able to remain in the community. Due to the unforeseen

service gaps created by this shift, many people became "lost" within the community service system. People not engaged through traditional outpatient services were soon engaged by the criminal justice system, returned to the hospital, or became "revolving door" consumers of emergency services.

Movement toward a community system continues, and has brought into question the need for long-term inpatient services. Numerous states have closed or are in the process of closing state hospitals and developing community-based services. Unfortunately, some of these closures have been premature due to a lack of planning and supports needed to support the transition. Consequently, increases in homelessness, a disproportionate presence of people with SMI in the correctional system, and personal tragedies have occurred due to ill-considered risk factors. No state has completely eliminated its need for longer-term institutional services, although the number of people served in such settings has been dramatically reduced. The mission of the remaining services is changing, from providing permanent domicile to returning people to the community.

### Recovery

The *recovery movement* is a social movement energized primarily by people with SMI, often known as "consumers" or "survivors" of mental health services. The movement has historical origins in the early 20th century, but has become most influential in national mental health policy over the past decade. Since the 1970s the recovery movement has been associated with psychiatric rehabilitation, to the degree that psychiatric rehabilitation has been characterized as "the technology of recovery." No comprehensive definition of *recovery* exists, but all definitions advocate as a goal that the client will gain autonomy and independence. This contrasts with the traditional "medical model" goals of controlling symptoms and preventing relapse or hospitalization. The recovery concept provides a sense of hopefulness to people with SMI, with the idea that their diagnosis is not a terminal condition but rather one of possibility. It holds that people are more than their diagnosis, and counters the stigmatization that they are somehow the cause of their disabilities. The concept emphasizes that people with SMI must have a voice in their treatment and rehabilitation, and a sense of responsibility, instead of being passive recipients of services. The recovery movement gained a

national forum in the United States in the 1999 Surgeon General's Report on Mental Health, and more recently in the report of the 2003 President's New Freedom Commission on Mental Health.

The report of the president's commission calls for a national effort to strengthen the evidence base for rehabilitation and recovery methods, and to accelerate their dissemination. However, all aspects of research and treatment development have been vigorously criticized as lacking sufficient client participation. As with psychiatric rehabilitation research in general, the research that supports recovery would benefit from more systematic inclusion of clients' perceptions of and experiences in actual treatment and other services.

## SECONDARY TRAUMA

Secondary trauma is the emotional spread of the effect of trauma symptoms as a result of close and extended contact with traumatized individuals. Generally, the traumatized person has close and extended contact with others, such as family members, friends, or mental health professionals. These individuals are at risk of experiencing psychological distress through direct exposure to the traumatized person. Symptoms of secondary trauma are similar to those of posttraumatic stress disorder (PTSD), but are less severe. Symptoms of secondary trauma include having unwanted thoughts or images about the trauma incident, persistent avoidance of places or activities related to the traumatic incident, detachment from others, and increased arousal indicated by sleep disturbances, irritability, concentration difficulties, or being overly vigilant.

The term *secondary trauma* has been used to encompass both vicarious trauma and compassion fatigue. *Vicarious trauma*, like secondary trauma, refers to the experiencing of trauma symptoms caused by close association with a traumatized person. *Compassion fatigue*, on the other hand, refers to the acquisition and development of symptoms by mental health professionals who are engaged in a therapeutic relationship with traumatized individuals.

### Vicarious Trauma

Secondary trauma symptoms have been found in individuals who live with a traumatized family member, were raised by parents who were traumatized, or grew up with parents who were traumatized war veterans. Children of Holocaust survivors have been shown to acquire secondary trauma symptoms via intergenerational transmission; that is, the emotional and behavioral symptoms exhibited by family member(s) of one generation have been found to pass on to those of the next generation. Individuals in relationships with traumatized persons are also likely to acquire trauma reactions. It was found that when one partner reported a history of childhood physical or sexual abuse, the other partner reported significant symptoms of psychological distress. Research thus suggests that being in a family with someone who has been traumatized puts one at risk of developing vicarious trauma.

There are two hypotheses as to how exposure to a traumatized family member leads a person to acquire

and experience vicarious trauma. The first suggests that the emotional bond between family members is the avenue through which the traumatized person's symptoms are transmitted to others in the family. Underlying a caring relationship is sympathy and empathy. Empathy is similar to sympathy, but goes beyond sympathy in that empathy involves vicariously experiencing the thoughts, feelings, and experience of another. It is not surprising that individuals are vulnerable to acquiring and experiencing vicarious trauma from a family member, since being in the same family implies close and regular contact. In addition, family systems are usually one of the primary social support networks that individuals turn to for support and caring in times of difficulties and distress. Family members are likely to want to know what happened during the traumatic incident, how the traumatized person has been negatively affected, and what behavioral and emotional symptoms have developed. By virtue of being emotionally connected, a family member may feel the pain of the traumatized person to the extent of experiencing similar trauma symptoms.

Another hypothesis is that being exposed to a traumatized person can cause a family member to formulate beliefs about him- or herself, others, or the world in general that predisposes the family member to acquire and experience secondary trauma symptoms. For example, in incidents in which individuals are brought up by parents who have been traumatized by war or other atrocities, they may view the world as an unjust and unsafe place in which catastrophic and uncontrollable events can suddenly occur. These are similar beliefs often held by traumatized individuals that perpetuate trauma-related symptomology.

### Compassion Fatigue

Working with individuals in a therapeutic relationship can be fulfilling and rewarding, as the therapist facilitates healing and recovery in clients who suffer from the psychological aftermath of having experienced a traumatic incident. However, being in such a helping role sometimes causes emotional pain due to direct exposure to the client's traumatic material. Compassion fatigue is therefore an occupational hazard of being in the role of providing therapeutic help. Research has found that many sexual assault trauma counselors develop intrusive and unwanted images similar to those of their clients. Other research has indicated that female psychotherapists who work with large numbers of

sexual abuse cases, or have seen a high number of sexual abuse survivors over the course of their careers, are more likely to develop and experience trauma symptoms than those who see fewer sexual abuse cases.

As to how or why psychotherapists who work with traumatized clients are vulnerable to develop symptoms of compassion fatigue, the first explanation, which involves empathy, is similar to the one mentioned for vicarious traumatization. Empathy is a major resource for psychotherapists in helping the traumatized, given its centrality in comprehending the experience and perspectives of clients. Empathy is indispensable in establishing rapport in a therapeutic relationship, assessing presenting problems, and formulating a treatment approach. While empathizing with a traumatized client helps the therapist to understand the client's experience of being traumatized, the process may traumatize the therapist. Another reason why working with traumatized individuals can cause impairment in therapists is that exposure to clients' trauma may provoke or reactivate unresolved issues from therapists' own trauma histories.

### Compassion Fatigue Versus Burnout

Compassion fatigue is not to be confused with burnout. While these are both occupational hazards of being a psychotherapist, they are different from each other. Burnout is a process that begins gradually and gets worse over time. The literature on burnout supports the notion that the process is set in motion by gradual exposure to job strain, loss of idealism, a lack of sense of accomplishment, and accumulation of intensive contact with clients, particularly those whose problems are perceived as chronic, acute, complex, and require skills beyond what the therapist possesses. The causes and mechanisms leading to symptoms of compassion fatigue, as mentioned above, are quite different from those leading to burnout. Secondary trauma symptoms (STS) precipitated by compassion fatigue can emerge suddenly without warning. STS can happen to a psychotherapist at any point of his or her career. Additionally, STS also has a faster recovery rate than burnout.

### Assessing Secondary Trauma

Despite the importance of studying secondary trauma, given its major impact on family members, close friends, and psychotherapists, there are few psychometrically

sound instruments to assess this type of traumatization. Most of the existing instruments are designed for specific populations, such as mental health workers or children of Vietnam veterans who were diagnosed with PTSD. Another problem is that existing measures often lack reliable cutoff scores to facilitate clinical decision making. In some cases, both limitations are present. The Secondary Trauma Scale (STS) was developed to address these limitations. When the 18-item secondary trauma scale was administered to a university-age sample (along with other instruments to measure anxiety, depression, and symptoms of intrusiveness, avoidance, and dissociation), initial results indicated that higher scores on the scale were associated with emotional distress and intrusive and avoidance symptoms.

In summary, because most individuals turn to their existing social support networks in times of crises or distress, clinical attention should also be extended to those who provide care and support to those traumatized directly, such as family members. Given that compassion fatigue is a natural by-product of working with and caring for traumatized individuals, it should be recognized as the cost of caring for mental health professionals and addressed openly in training programs to prepare them to cope with these issues in the future. Secondary exposure to trauma may cause helpers to inflict additional pain on their clients, lose objectivity, or suffer negative impact on their own well-being. Treating and preventing such occupational hazards is important for sustaining helpers' longevity and effectiveness. Given the impact of secondary trauma, more research attention should be directed at validating psychometric instruments to measure the severity of secondary trauma in order to facilitate appropriate intervention and treatment.

## SELF-DISCLOSURE

---

Self-disclosure refers to the verbal disclosure of personally sensitive information by client or counselor, and may involve disclosure about actions, thoughts, or feelings.

The necessity of client self-disclosure in counseling has a long tradition, beginning with Sigmund Freud, who asserted that clients should disclose everything that comes to mind. This expectation persists to the current day. Practitioners who follow a range of counseling approaches agree that counseling would not be successful without client self-disclosure, for healing occurs through the discussion of personally sensitive content and the resolution of concerns related to that content. This belief in the healing potential of disclosure is not universally supported, however, for some counselors believe that clients' views of themselves suffer when they reveal shameful material.

Client self-disclosure has been the focus of extensive research, beginning with the work of Sidney Jourard, who investigated what information clients reveal, and to whom. The research evidence demonstrates that most clients reveal intensely personal material, and their disclosures focus on aspects of themselves or their parents that they dislike.

Nevertheless, half of all clients keep secrets from their counselor, often about sexual concerns, relationship problems, or a sense of failure. Both sexes disclose equally and in similar areas, and the longer clients are in counseling and the stronger they experience the counseling relationship, the more they disclose.

Although client self-disclosure is largely seen as necessary for successful counseling, counselor self-disclosure is viewed as a controversial, but potentially powerful, intervention. Some of this controversy reflects the different theoretical approaches to counseling.

Counselors following a psychodynamic approach limit their use of self-disclosure, believing that a neutral, abstinent, and anonymous counselor is necessary for resolving client transference. Humanistically and existentially oriented counselors evince stronger support for self-disclosure, viewing it as a way for counselors to demonstrate their genuineness and positive regard, show the counselor as human, and reassure clients that their concerns are normal. Counselors who follow behavioral, cognitive, or cognitive-behavioral approaches view self-disclosure positively when it is intended to model client self-disclosure. Feminist counselors assert that disclosures are helpful because they equalize power in the counseling relationship and allow clients to make informed decisions about whether to work with a counselor. Finally, those who follow a multicultural approach support self-disclosure as a means of earning clients' trust, especially when working with clients from different sociocultural backgrounds.

Research regarding counselor self-disclosure has examined the frequency of and reasons for self-disclosures, and their immediate and longer-term effects. Regardless of theoretical orientation, counselors disclose infrequently and their disclosures focus mostly on professional background. Their goals are to give information to clients, reassure clients that their experiences are normal, model appropriate self-disclosure, and strengthen the counseling relationship. Counselors avoid disclosure when doing so would meet their own needs or shift the focus from clients. Nonclients (e.g., undergraduates) view counselor self-disclosure positively and like counselors who self-disclose neither too much nor too little. Clients perceive counselor self-disclosure as helpful with regard to immediate outcome, but the longer-term effects are unclear.

## SELF-EFFICACY/ PERCEIVED COMPETENCE

---

First developed in 1977, self-efficacy is an important component of Albert Bandura's social cognitive theory. Self-efficacy refers to people's judgments of their ability to perform necessary behaviors to produce desired outcomes in specific situations. These judgments are highly context specific and tend to influence which activities people will attempt, how much effort they will put into the activities, how long they will persist at them, and their emotional responses while involved in the activities. For example, adolescents who feel more efficacious about their writing abilities than their math skills will be more likely to (a) take writing classes and avoid math classes, (b) exert more effort in their writing classes than math classes, (c) experience more anxiety in math than writing classes, and (d) persist longer in writing than math classes when they encounter difficulties.

### Dimensions of Self-Efficacy

Self-efficacy beliefs vary on three dimensions: magnitude, strength, and generality, although the strength dimension is employed most widely in self-efficacy measures. Nonetheless, all three dimensions have potentially important implications for performance. The magnitude dimension encompasses the number of steps, or level of task difficulty, people consider themselves capable of performing. Some people limit

themselves to attempting only simple tasks while others attempt the most difficult and complex tasks. For example, a person trying to lose weight may feel efficacious to abstain from eating sweets when there are no sweets present. However, that person may feel less efficacious to pass up the dessert cart at a restaurant.

Efficacy beliefs also vary in strength. People with weak efficacy beliefs are easily discouraged by obstacles and setbacks, while people with strong efficacy beliefs persevere despite disconfirming experiences. For example, two people wanting to abstain from sweets may feel they can pass up the dessert cart at a restaurant, but one may hold this belief with more certainty.

Finally, efficacy beliefs vary in generality. Self-efficacy beliefs in one behavioral or situational domain may generalize to other behaviors or situations depending on the extent to which those behaviors and situations require similar skills. For example, the person able to pass up the dessert cart may also feel efficacious in passing by a bakery without walking in.

### Sources of Self-Efficacy

A strong sense of efficacy can be developed in four ways: mastery experiences, vicarious learning experiences, social persuasion, and physical and emotional states.

#### **Mastery Experiences**

Mastery experiences are personal experiences that give people a sense of accomplishment and a feeling of mastery. By managing challenges through successive achievable steps, people develop a sense of mastery. Mastery experiences are the most effective way to develop a strong sense of efficacy because they offer the most authentic evidence that one can do what it takes to succeed. Success experiences help build self-efficacy, while failures undermine it. For example, using the weight loss example, a person who has lost weight in the past is more likely to have higher self-efficacy in this area than someone who has not been able to lose weight previously. Success experiences need to be at least somewhat challenging in order to develop a strong sense of efficacy. Easy successes can lead to expectations of quick results, which may lead people to become easily discouraged when faced with obstacles or setbacks. Overcoming obstacles through perseverance teaches people that success often requires sustained effort, which, in turn, creates

resilient self-efficacy beliefs. Once people develop a strong sense of efficacy, they persevere when facing difficult tasks, work harder to overcome obstacles, and rebound quickly from setbacks. The negative impact of occasional failures is diminished.

The effects of failure on efficacy beliefs depend in part on when they occur. If failures occur before a resilient sense of efficacy is established, they will undermine self-efficacy. The person will be less likely to do what it takes to overcome obstacles and rebound from setbacks. However, if a resilient sense of efficacy has already been established, the person will work hard to overcome obstacles and rebound easily from setbacks, thus increasing self-efficacy even more.

#### **Vicarious Experiences**

Mastery experiences are not the sole source for developing a strong sense of efficacy. Vicarious experiences through social modeling are another way to develop self-efficacy. If people see others similar to themselves succeed through persistent effort, they may come to believe they, too, can succeed in similar activities. The impact vicarious experiences have on self-efficacy depends on how similar to the model people perceive themselves to be. The greater the perceived similarity, the more impact the model's successes and failures will have on a person's self-efficacy beliefs. People seek models proficient in the skills and abilities they wish to acquire. Competent social models may help increase efficacy by teaching skills and strategies for managing the demands of the environment. For example, let's say that the person who wants to lose weight has a friend who has lost weight. If that friend has a similar build, eating habits, or lifestyle, the person may feel more efficacious in his or her own ability to lose weight.

Social models also provide a gauge by which people judge themselves. Many times adequacy in specific areas is gauged in relation to the performance of similar others. This is called *social comparison* and is a primary factor in the self-appraisal of abilities. For example, an art student who compares himself to other art students rather than to Picasso or his 3-year-old nephew will more likely develop an accurate sense of efficacy on artistic tasks. Comparing one's artistic talents to Picasso will undermine efficacy beliefs, while using one's 3-year-old nephew as a model will lead to unrealistically high self-efficacy beliefs. Such social comparison information can have far-ranging consequences on the types of activities people choose to

pursue and on their feelings of efficacy regarding those pursuits.

### ***Social Persuasion***

The third source for developing a strong sense of efficacy is social persuasion. People can lead others, through suggestion, into believing they have the ability to do what is necessary to accomplish a certain outcome. While social persuasion is not as effective as mastery or vicarious experiences, often people can be verbally persuaded that they possess the ability to master certain activities. People who are persuaded in this manner are more likely to sustain effort and try harder when faced with obstacles. People who want to effectively persuade others should arrange situations and events in ways that promote success and avoid placing people prematurely in situations where they might fail. The strength of social persuasion depends on factors such as the perceived expertness, trustworthiness, and attractiveness of the persuasive source.

### ***Physical and Emotional States***

The final source for developing a strong sense of efficacy is to reduce stress and depression while increasing physical stamina. People use their physical and emotional states to judge their capabilities. An elevated mood can enhance self-efficacy, while a negative mood may diminish it. People tend to associate stress, tension, and other unpleasant physiological signs with poor performance and perceived incompetence. In activities requiring strength and stamina, feelings of fatigue and pain cause self-efficacy beliefs to decrease. How an emotion is perceived and interpreted is more important than the level of intensity. People with a strong sense of efficacy are more likely to view their state of emotional arousal as energizing, while people with a weak sense of efficacy will view their state of emotional arousal as debilitating.

## **Mediating Processes**

Self-efficacy beliefs regulate human functioning through four major types of processes: cognitive, motivational, affective, and selective.

### ***Cognitive Processes***

A key purpose of thought is to enable people to visualize possible outcomes of different courses of

action. It allows people to exercise control over activities that are important to them. Most courses of action are first preceded by thoughts. These thoughts become guides for action when developing skills. Self-efficacy beliefs influence thoughts in ways that can either bolster or impair performance. People's self-efficacy beliefs influence how they visualize future events and approach potential situations. Self-efficacy and visualization are bidirectional. High self-efficacy beliefs foster positive visualizations and positive visualizations strengthen self-efficacy beliefs. People with high self-efficacy beliefs in a specific domain display greater cognitive resourcefulness, more flexibility, and an ability to manage their environment in that domain. They set higher goals for themselves and have a stronger commitment to those goals. People with high self-efficacy visualize themselves navigating those situations successfully. These positive visualizations enhance subsequent performance. People with low self-efficacy in a specific domain are more likely to visualize failure scenarios in that domain. They tend to dwell on personal deficiencies and what is likely to go wrong. This undermines motivation.

### ***Motivational Processes***

According to Bandura, there are three different forms of cognitive motivators, each with a corresponding theory. The motivators are causal attributions, outcome expectancies, and cognized goals. The corresponding theories are attribution theory, expectancy-value theory, and goal theory. In attribution theory, causal attributions of performance affect motivation. Attributions are the explanations people give for behaviors or events. Efficacy beliefs influence these causal attributions. People with low self-efficacy attribute their failures or setbacks to low ability, while people with high self-efficacy attribute failures or setbacks to too little effort or ineffective strategies. People with high self-efficacy believe that success is a matter of more effort or better strategies.

In expectancy-value theory, people are motivated by the outcomes they expect to achieve through specific courses of action. The strength of the motivation is based on two factors: the expectation that a specific action will produce a specific outcome and the attractiveness of that outcome. The more people expect that their behavior will secure a specific outcome and the more highly valued the outcome, the greater their motivation will be to perform the activity.

Goal theory suggests that explicit, challenging goals based on personal standards enhance motivation. Motivation based on these personal standards involves comparisons between people's adopted personal standards and their perceived performance. In order to evaluate how they are doing, people set personal standards and judge how well they are performing against those standards. Self-efficacy beliefs play a key role in this form of motivation. Often, people choose goals based on their self-efficacy beliefs. How efficacious people feel will influence what challenges they choose to undertake, how much effort they will expend, and how long they will persevere in the pursuit of their goals.

### ***Affective Processes***

Self-efficacy is an important component to the self-regulation of emotional states. Efficacy beliefs affect the nature and intensity of emotional experience through a person's ability to control thought, action, and affect. Efficacy beliefs influence where people place their attention and whether situations will be construed as benign or distressing. People's belief in their ability to cope affects how much stress, anxiety, or depression they will feel. People with high coping efficacy behave in ways that make difficult situations more manageable. According to Bandura, often the distress people feel results from failures to control upsetting thoughts. People with strong coping efficacy are more able to control such thoughts.

### ***Selection Processes***

By selecting their environments, people have a choice in what they become. Choices are influenced by self-efficacy beliefs. Self-efficacy beliefs influence the types of activities and environments people choose to become involved in, as well as the environments they actually produce. People shape their lives by choosing environments that encourage certain capabilities and lifestyles and avoid activities and environments they believe to exceed their capabilities.

## **Self-Efficacy and Mental Health**

Three major types of self-efficacy have been identified: task-specific self-efficacy, self-regulatory efficacy, and coping efficacy. Task-specific self-efficacy refers to people's beliefs in their ability to perform the specific tasks required to succeed within a given domain.

Self-regulatory efficacy is defined as people's perceived ability to guide and motivate themselves to perform self-enhancing behaviors. Coping efficacy refers to people's beliefs in their ability to deal with particular obstacles. Research shows that coping efficacy is significantly related to mental health.

### ***Coping Efficacy, Stress, and Anxiety***

Individuals encounter stressors on a daily basis. These daily stressors have been found to be important indicators of psychological distress. People's beliefs in their ability to regulate their functioning, exercise control over their environment, and manage the stressors in their lives affect their psychological well-being. Strong coping efficacy has been shown to reduce stress reactions. People are less likely to feel stress when they believe they can handle the task or situation. Researchers have found that when people have low coping efficacy, their distress significantly increases when faced with stressors. However, if people's perceived coping efficacy is strengthened, they will display less stress and physiological arousal when faced with the same stressors. Perceived self-efficacy is also related to people's approach to coping with stressful situations. People with high coping efficacy are motivated to change the harsh environment and stressful situation. Through increasing or maintaining their coping efforts, they alter stressful situations into more benign ones, thus alleviating their stress.

Anxiety is a psychological problem that is often a result of stress. Anxiety is aroused when people feel they are unable to cope, either cognitively or behaviorally, with potential threats. Bandura argued that low coping efficacy beliefs regarding difficult circumstances cause anxiety and avoidant behaviors. People who believe they can control their environment and cope with the potential threats are less likely to feel anxious. People with low coping efficacy tend to view potentially threatening events as unmanageable, perceive situations as fraught with dangers, and exaggerate the severity of potential threats. They become distressed and experience high levels of anxiety. People tend to avoid situations that cause them anxiety or potential anxiety.

### ***Self-Efficacy, Coping Efficacy, and Depression***

Perceived self-efficacy plays an important role in depression. Three types of self-efficacy beliefs

influence depression. First, people may feel unable to perform at a level that would bring them personal satisfaction. Second, people may feel incapable of developing meaningful relationships with others. Third, people may feel unable to control depressive thoughts. According to Bandura, there is a relationship among self-efficacy expectations, outcome expectations, outcome value, and depression. If people believe that a highly valued outcome is obtainable through specific behaviors, but believe they are not capable of performing those behaviors, depression and self-devaluation may occur.

Bandura and his colleagues have found that perceived academic self-efficacy and social self-efficacy, which address two important aspects of adolescents' lives, affect adolescents' depression both directly and indirectly. Perceived academic and social self-efficacy affect depression directly via their influences on adolescents' mood and emotional states. Perceived academic self-efficacy has an indirect effect on depression via its impact on adolescents' engagement in behaviors that lead to academic achievement. A strong sense of academic efficacy also affects depression by decreasing adolescents' academic stressors and promoting motivation and confidence in their abilities. High social self-efficacy reduces adolescents' vulnerability to depression by promoting supportive relationships with peers. Furthermore, perceived academic self-efficacy and social efficacy can be buffers to prevent adolescents from risky activities, such as delinquency and substance abuse, by reducing their risk of depression, promoting academic achievement, and developing peer support. It is also important to note that the relationship between self-efficacy and depression is not limited to adolescents or young adults. Among senior citizens, self-efficacy has been found to significantly predict depression, beyond what could be predicted by demographics, income, or health.

### ***Coping Efficacy and Life Transitions***

Perceived coping efficacy serves as a regulatory function in the transitions of life. It is especially important during the transition process from adolescence to adulthood, which can be full of stress, challenge, and risk. Adolescents with high coping efficacy tend to cope with the transition well. They pursue activities that build competencies and resist peer pressure to engage in risky behaviors.

Coping efficacy can also promote mental health later in life. Seniors with high coping efficacy beliefs are more likely to adapt readily to the challenges of aging. They engage themselves and their environment to facilitate the transition process by improving and maintaining physical health, improving social skills, and enhancing cognitive functioning.

### ***Coping Efficacy and Trauma***

Each year millions of people experience traumatic life events such as natural disasters, sexual or physical assaults, or the death of a loved one. Even long after the trauma, people may show signs of stress by experiencing recurrent nightmares, flashbacks of the event, and sleep disturbances. Research has shown that people's beliefs in their ability to exercise some control over their personal functioning and environment after the event have an impact on their posttraumatic recovery. Traumatic events alone are not enough to cause stress or disorder. People's appraisal of the event substantially contributes to the emotional well-being following it. People with high self-efficacy in their ability to control their environment and recover from traumatic events tend to experience less distress and make efforts to effect changes in their lives.

### ***Implications***

It has been shown that high coping efficacy can reduce people's vulnerability to stress and depression, enhance their resiliency to adversity, and improve their mental health. Thus, increasing coping efficacy can be a focus of intervention for counselors. The first task for counselors is to assess their clients' perceived coping efficacy through questions about the clients' beliefs in their competence in behaviors related to coping with stressful events. When counselors find that clients unrealistically underestimate their capabilities, counselors may focus on the causes of these perceptions by exploring clients' culture, family background, and previous experiences. Thus, in the assessment stage, counselors try to help clients identify areas of vulnerability and explore areas of behavior where they feel an inability to cope with stress.

In addition to informal assessments or discussions with clients, counselors can use developed instruments to assess clients' self-efficacy. Since self-efficacy is not a global trait, but an individual's belief related to distinct behavioral domains, there is no single measure

of self-efficacy that can be used across different contexts. Self-efficacy measures have been developed for various domains. Self-efficacy instruments in the career domain have been developed to assess clients' efficacy about their decision-making abilities (e.g., career decision making self-efficacy) and activities involved in specific career fields (e.g., mathematics self-efficacy) as well as career fields themselves (e.g., engineering self-efficacy). In addition, self-efficacy scales have been developed to assess social efficacy, coping efficacy, and a variety of other domain-specific tasks (e.g., computer, weight loss, and smoking cessation self-efficacy beliefs).

Once the counselor and client decide on a domain of behavior in which to strengthen self-efficacy, it can be beneficial to the client's psychological adjustment and well-being to move to an intervention stage. In this stage, counselors help clients build higher levels of self-efficacy. It is helpful to use the four sources of self-efficacy—mastery experiences, vicarious experiences, social persuasion, and physical and emotional states—as a framework for this stage.

Counselors can help clients recall and process previous successful experiences as a way of motivating clients to face future challenges. In addition to helping clients explore their previous successful experiences, counselors can also focus on facilitating future achievement. Counselors can help clients make plans and strategies to achieve their goals. They can help clients break down difficult tasks, behaviors, or goals into smaller, more easily manageable steps. They can provide relevant resources, if necessary, to help clients gain success experiences.

Counselors can help clients increase their self-efficacy by the use of vicarious experience. Counselors can help clients find social models in their environment by helping them identify people who have succeeded in the behavioral domains where the client lacks self-efficacy. The more similar to the model the client feels in terms of gender, ethnic group, and background, the more influence the model will likely have on the client. Models can be family members, friends, or even people from the media.

The third source of efficacy is social persuasion. Counselors can strengthen clients' self-efficacy by expressing their belief in the clients' capabilities, encouraging them, and reinforcing their efforts. In addition to the encouragement and support that is vital to clients' progress, counselors can also help clients set realistic goals, discuss possible barriers to achieve

the goals, help clients find ways to cope with and overcome these barriers, and attribute success experiences to growing competency rather than to such other factors as good luck and tasks that are too easy. It should be noted that the role of the counselor is not just to convey positive appraisals, but rather to realistically boost clients' self-efficacy, and to help clients improve their coping skills.

Finally, as mentioned earlier, people tend to depend on their physical and emotional states to judge their capabilities. They may interpret their emotional arousal as a sign of poor performance. Therefore, counselors can help clients increase self-efficacy by teaching them techniques to reduce stress and emotional arousal. Some of these techniques include anxiety management, relaxation training, and teaching clients more adaptive self-talk. Counselors can help clients become aware of their negative self-talk, and teach them ways to stop their self-defeating thinking patterns and replace the patterns with task-focused cognition.

## SELF-ESTEEM

---

Self-esteem is generally considered to be how individuals evaluate their self-worth and competence. This evaluation can be positive or negative. Having a positive sense of self or good self-esteem is linked to many positive behaviors, such as achievement, initiation, motivation, and good mental health. Not all researchers and clinicians, however, approach the study of the self or self-esteem in the same way, and this lack of consensus has led to the many measures that are available for trying to ascertain the level of self-esteem of individuals.

In the next sections of this entry the various ways of thinking about the self and self-esteem will be reviewed. There will be a brief history of self-esteem and a discussion of how to define *self-esteem* (and related terms). Finally, the issue of how to measure self-esteem and various measures that are currently being used to study self-esteem will be reviewed.

### A Historical Overview

The first glimpses of theoretical differences in explaining the self system can be seen beginning with the

mind-body debates of the Greek philosophers, Socrates, Plato, and Aristotle. These philosophers all theorized about where the “essence of a person” (the self) resided, in the soul or in the mind. Centuries later these early quests to understand the body and soul influenced other philosophers and scientists to examine what constitutes an individual’s “self-identity.” One of the most influential of these philosopher-scientists to discuss the self-concept in depth was William James in his 1890 book *The Principles of Psychology*. James is credited as the first psychologist to develop a theory of self-concept. It is his theoretical structure of self-concept that laid the groundwork for all of the other theories that have since been posited about this construct.

James incorporated his ideas of self into the concepts of “I” and “me.” The “I” is the subjective self and the “me” is the objective self. The “I” is the essence of the self or what constitutes one’s personal identity. It cannot be observed directly and, according to James, can only be discovered through reflection. The “me” is the combination of all things that are objectively known about the self; that is, those things that incorporate one’s material self, family, and friends and one’s social self. Unlike the “I,” the “me” can be observed and empirically examined.

There are three elements of the Jamesian “me”: the material “me,” the spiritual “me,” and the social “me.” According to James’s theory, these elements are ordered in a hierarchical structure with the material self at the bottom, the spiritual self at the top, and a combination of material and social elements in the middle. Self-evaluations then, according to Jamesian theory, are the reflection of how individuals weight the subjective importance of these different characteristics of the “me.” The importance placed on these characteristics becomes the standard that objective information is referenced against and dictates what is considered to be a success or a failure.

This overview of James’s theory regarding self-concept is only a brief summary of a very critical piece of work that has affected self-concept research throughout history, including contemporary times. Indeed, symbolic interactionists Charles Cooley and George Herbert Mead were influenced by the Jamesian concept of the “social self” when developing their theories on the impact of socialization. Cooley’s concept of the “looking-glass self,” for example, posits that individuals can only know themselves through the reactions and social interactions of others. Mead also considered social interactions

important to the development of the self but, like James, acknowledged a core self that is modified by these interactions. Other psychological paradigms as diverse as psychoanalytic and behaviorist theory were affected by James's framework of self-concept. Sigmund Freud and his followers, like James and Mead, believed that individuals were influenced by the way others view them or feel about them. They, however, added the idea that the self-concept exists at birth and is modified by childhood interaction with family members, especially the mother.

In contrast to the psychoanalytic theorists, behaviorists do not believe that individuals have an innate self. Instead, behaviorists such as John Watson and B. F. Skinner believed that individuals are the sum of all of their experiences, which are modified by positive and negative reinforcement from the environment. Individuals, therefore, interact with their environment and, through various forms of reinforcement, learn what is beneficial to their survival and continue those behaviors. By understanding these behaviors and social contingencies, individuals can begin to understand how they are different from others, and derive a sense of self. Therefore, self-development, according to behaviorism, occurs as individuals become active in creating an environment that is positively reinforcing to them.

These theoretical paradigms were not the only ones affected by the Jamesian structure of the self. Over the course of the last 3 decades, the research has moved away from the view that learning is affected by the environment only. Learning is now viewed as an interaction of cognitive processes and reinforcement from the environment. The area of self-concept research has followed the lead of the field. It is clear that the concept of self is part of the cognitive structure of a person. When individuals think of themselves, they have a mental representation of themselves. When they interact with others, they derive information from these encounters and modify how they view themselves and how they view others. In this way, individuals are processing information from their environment and either modifying existing thoughts or ideas or adding new ones. This information processing during important interactions is what is considered social cognition. Most of the theories from the literature today are based on some concept of social cognition.

The problem that social cognition addresses is whether individuals are accessing information about the self when answering questions or responding to statements that seek to gather information about either

self-concept or self-esteem. Thus, when attempting to gain any information from measures where individuals report on their own thoughts and feelings (self-report), the researcher assumes that some aspect of memory is being incorporated in the response. In general it is believed that information about this self is held in long-term memory. Some researchers, however, believe that the only way to answer questions related to self is to have this information assessable in short-term memory. Cognitive researchers make the argument that information on emotions, plans, and evaluations are generally held in short-term memory and, therefore, should be accessible during self-report assessments. They base their research on a general information-processing model that emphasizes the retrieval of information from the short-term memory.

## Definitional Issues

Self-definitions can be classified into uni- and multi-dimensional definitions. Early definitions of *self-concept* emphasized a general or overall self-concept that influenced individuals' reactions or behaviors over all situations. For example, people with a high sense of self-worth will deal more competently with all life events than will those who have a low sense of self-worth.

Since the 1980s, however, there has been a general shift away from these unidimensional definitions toward a more multidimensional view. The multidimensional definitions emphasize that individuals view themselves differently across situations. One may have a good self-concept of his or her reading abilities but not have one involving his or her math abilities. Hence, the behavior would be different depending on whether a person was dealing with a reading or math situation.

The dimensionality distinction is not the only one that has affected research on the self. A more difficult distinction to make when defining the self is whether it is evaluative or descriptive. Some researchers see this distinction as the difference between self-esteem and self-concept. Self-esteem, for example, is viewed as the degree of liking or satisfaction with the self (e.g., "I am a good person"). Self-concept, on the other hand, is more descriptive and can be evaluative (as in "I love math") or nonevaluative (as in "I am a boy"). Unfortunately, the difference between these two constructs is often just semantic. Individuals can describe themselves as both descriptive and evaluative at the

same time (e.g., “I am smart because I like to read”). It is important when defining the self to be explicit about which element of the self is being studied, the descriptive or the evaluative. Too many researchers are not making these distinctions and, therefore, are claiming to study the self-concept or descriptive self when they are actually gathering information on the evaluative self. Some of the confusion in these terms comes from the historical study of the self where philosophers and researchers tried to understand the nature of the self and its evaluative component, self-esteem.

### Methodological Issues

Classically, the way to measure the self and self-esteem is through some type of self-report methodology. Generally, self-report methodologies can be categorized as either reactive or spontaneous. The most often used as well as the more popular of these two methodologies is the reactive self-report. This type of self-report is characterized by a closed-ended response format that uses a Likert-type scale representing differing dimensions. In general, participants in a study are asked to react to questions or dimensions derived by the researcher and then to locate themselves on the scale provided. This type of methodology is usually easy to use, often creates little interaction between the participants and the researcher, and creates data that can easily be manipulated quantitatively. The majority of self-concept measures used in current research are considered reactive.

The spontaneous approach allows the participant rather than the researcher to create the dimensions that are examined. This approach is often labeled “open-ended” because participants are allowed to answer in unconstrained ways. In this approach, participants generally answer a vague question such as “Who are you?” without any constraints as to how long they answer or how much they answer. In some situations boundaries are established for the amount of time or numbers of answers that are given. The spontaneous approach, generally, is more difficult to score and summarize than is the reactive and usually involves a great deal of interaction between the participant and the researcher.

The decision of what type of methodology to use is dependent on what type of process the researcher is attempting to examine, descriptive or evaluative. Some researchers believe that these two processes tap into different aspects of the self. Hence, by using only

evaluative measures, important information about the construct of the self is lost. Thus, it is important to understand which aspect of the self is being studied, and this is an important distinction to keep in mind when deciding on what type of methodology to use when examining self. Other issues that are also important to the measurement decision are discussed below.

Even though self-report is not the only methodology used for gathering information on children and adults, it is often the most used in the literature and consistent with theoretical concepts on how to retrieve information about the self. There are inherent problems, however, in dealing with this type of methodology. Issues such as how accessible this information is in the memory when being asked these questions, the situations or contexts a person is in when answering these questions, and other individual or developmental differences that might influence how one answers questions about the self are important factors to consider.

The accessibility of the self refers to the cognitive processes involved in how information about the self is distributed and processed through the memory and how easily it is retrieved when queries regarding the self are made. Due to the reliance on memory in examining the self, there are inherent biases such as self-deception that occur when trying to access this information.

In general, because obtaining information about the self involves cognitive processes that have to be accessed and organized, researchers who study the self need to be aware of the biases that can occur in self-reports. In general, information that is easily accessible, that involves information about the self that is attended to on a regular basis, and that agrees with standard norms is more likely to be reported than information that does not meet these criteria.

The second area of concern in using self-reports involves the contextual, situational, and cultural factors that influence how individuals respond to questions about the self. If individuals are asked questions about the self when they are at work then they are more likely to discuss themselves in terms that define them in that environment. Information about the self can also be affected by the emotional state (good or bad moods) of an individual, how individuals want to be perceived by the researchers (self-presentation), and the culture of the individuals. The view that context, situation, and cultural factors influence the self is highly consistent with the symbolic interactionist ideas that were posited by Cooley and Mead. When

studying the self, it is important to understand the environmental and cultural norms that may be affecting the responses that individuals give to questions regarding the self. These factors may be contributing to the actual development of self-esteem or may be biasing the responses that are given.

## Self-Esteem Measures

Almost everyone will be given some form of a self-esteem measure at some point in their life. Self-esteem plays a central role in our understanding of human behavior, and it is important that care is taken in choosing the right instrument for measuring this characteristic. The following section examines a representative sample of self-esteem measures that are widely used and readily available.

Perhaps the most famous and widely used unidimensional measure is the Rosenberg Self-Esteem Scale that was developed to study adolescents but is now used across the whole age range. The Rosenberg is a 10-item scale that asks individuals to rate themselves using four categories (*strongly agree* to *strongly disagree*) on a series of questions regarding their sense of self-worth or confidence (e.g., “I feel that I’m a person of worth, at least on an equal plane with others”). This scale has been widely used in all areas of psychology, is easy to administer, and can be adapted to be used with children as well as adults. It is considered a highly reliable and valid measure of self-esteem. The measure is especially useful for getting a global sense of how a person feels about him- or herself and is a good predictor of other measures of mental health such as depression and anxiety. It is not a good predictor of more specific domains like academic ability or body image.

Another widely used unidimensional measure is the Coopersmith Self-Esteem Inventory. This inventory was developed for use with children but now is used with both children and adults. The inventory assesses subjects’ general attitudes toward themselves and in comparison to significant others in their lives. This scale contains around 50 items (even though this has been adapted across time) and individuals rate these items as being *like me* or *not like me*. The Coopersmith has good reliability and validity. Like the Rosenberg, this scale has been used effectively to ascertain a global sense of self-worth but not in predicting more specific domains of self-evaluations.

Overall, unidimensional scales are appropriate and useful for gathering information on the general

mental health of individuals. These scales were developed and based on assumptions that global self-esteem can be predicted across domains and be influential even to specific evaluations of domains such as achievement. However, psychological research has found that this is not the case, and a more multidimensional scale needs to be used when examining specific domains of functioning (e.g., achievement or sports).

As with the unidimensional scales, the multidimensional scales that are mostly widely used originated with work with children and adolescents and were adapted for use with other older and younger populations. These scales assume that individuals evaluate themselves differently across important areas of their lives. For example, they may evaluate themselves negatively on academics but positively on physical activities. The most noted of these scales is the Harter Self-Perception Profiles, which were originally designed for children but have been adapted and validated for adolescents, college students, adults, the elderly, and learning disabled students. In general, this measure assesses domains of cognitive, social, and physical perceived competence as well as general feelings of self-worth. The domains measured and numbers of items vary by the form that is used, but in general the scale contains 28 items. Each item consists of two paired alternative statements regarding the domains that are being measured (e.g., “I am good at reading” or “I am not good at reading”). Individuals are instructed to pick one of these items and rate it using response categories range from *really true for me* or *sort of true for me*. These measures have good reliability and have been validated across multiple studies.

The Self-Description Questionnaires created by Herbert Marsh and colleagues is similar to the Harter scales in that multiple dimensions are examined and the scales have been found to be reliable and valid for use with individuals ranging from childhood into adulthood. The dimensions vary across the age range, but in general scores can be obtained on individuals’ self-evaluation of academic ability, physical ability, physical appearance, relations with same and opposite sex peers, relations with parents, religion/spirituality, honesty, emotional stability, and general self-worth. Depending on the age of the respondent, the measure varies from 64 to 134 items regarding ability (e.g., “I am good at running”) that are rated from as *definitely false* to *definitely true*. The scaling varies from 5-point scales for the youngest children to 8-point scales for adolescents and adults.

These scales are just a small example of what is available for examining self-esteem. They were chosen because they have been used across multiple populations, and due to their popularity, there is information on how reliable and valid these measures are for use with various groups in the population. However, a simple search of the literature in self-esteem will uncover many more scales that are available for examining various aspects of self-esteem. Care should be taken in ascertaining that these measures are appropriate for use with various populations and have been shown to measure what they purport to measure. It is important for researchers and clinicians to use measures that are specific to the type of issue they want to understand, whether it be a global sense of self-worth or more specific evaluations of competencies across a wide spectrum of behaviors.

### Future Directions

Over the course of time the theoretical paradigms involving the self have taken their structure from the early works of William James and have built upon each other to form the contemporary theories that today are based on cognitive processing of aspects of the self. However, debate about what constitutes the self continues. Historically, the idea that social interactions play an important role in the development of the self has had strong support, but the exact nature of what constitutes the self remains vague. What is generally agreed upon, however, is that understanding the self involves understanding the separation of the descriptive and evaluative self. This distinction has a direct impact on the methodology that is used to gather information on the self.

The methodological issues are an especially difficult problem for research on the self. Even though the research history on self and the self-concept is vast, there are still many such issues on how to best measure this phenomenon. It is clear that the self develops across time and also changes (perhaps frequently) during that time, and thus measures that can examine this development are important but are difficult to find and confounded by the abilities of each age group. Many of these issues can be resolved by paying strict attention to the research methodology and psychometrics involved in obtaining information from self-report methodologies. Others, however, are more complicated and involve the theory and definitional differences in those who study the self and related constructs.

The problems of measuring a construct like self-esteem are inherent in all studies that try and examine and predict elements of the personality. Some researchers assume that phenomena that occur at the cognitive level will be manifested by behaviors that can be observed and measured. Others feel that behaviors should not be used to measure personality traits because we are unable to determine what cognitive processes might be affecting that trait. They argue that constructs like self-esteem should not be studied because there is no clear way to measure them or even know if you are measuring the right thing. Most people, however, can name many situations where they have observed behaviors of children, friends, and family members and suspected that these behaviors emanate from some activity involving their self-esteem. Therefore, there are observable behaviors that can be directly attributable to how people conceive of themselves.

As the majority of the theories suggest, individuals develop their self and self-concept through social interaction. There may be some innate cognitive process that is modified by social interaction or just social interaction, but either way people display behaviors and express opinions about who they are, from a very young age. For this reason it is important that psychologists be able to study and measure this phenomenon. Future work needs to address the issues of theory, definition, and methodology that have remained unresolved across the centuries. A consensus on these issues will lead to better measurement and a better understanding of how self-esteem influences the mental health and behavior of individuals.

## SELF-ESTEEM, ASSESSMENT OF

---

Self-esteem is one of the most widely studied variables in the social and behavioral sciences. A vast literature spanning many disciplines has shown that high self-esteem promotes behaviors, goals, and coping mechanisms that facilitate success in school, work, and relationships. High self-esteem impedes mental and physical health problems, delinquency, substance abuse, and antisocial behavior. Given its importance, it is not surprising that researchers have developed a diverse array of scales and procedures to assess self-esteem.

This entry discusses the issues involved in assessing self-esteem and provides an overview of the leading self-esteem measures used by psychologists. The entry begins by explaining what psychologists mean by the construct of self-esteem. Next it provides an overview of the most commonly used measures of self-esteem. The entry ends by briefly addressing several broader questions that bear on the interpretation of self-esteem measures and their use in research and applied contexts, including, Is self-esteem a stable trait or a transient state? How large a concern is socially desirable responding? Can self-esteem be assessed in young children? Does self-esteem vary as a function of age, gender, social class, and ethnicity? How does self-esteem differ from other aspects of personality, such as narcissism and neuroticism?

### Conceptualizing Self-Esteem

Self-esteem is generally conceptualized in terms of phenomenological experience. At the turn of the 20th

century, William James defined *self-esteem* as the degree to which people perceive their accomplishments as consistent with their goals and aspirations. In the mid-1980s, Morris Rosenberg extended this definition by adding that self-esteem involves feelings of self-acceptance, self-liking, and self-respect. These definitions have been applied to both global and domain-specific self-esteem. Global self-esteem refers to an individual's overall evaluation of him- or herself. Domain-specific self-evaluations focus on a specific facet of the self, such as physical appearance or academic competence.

The conceptualization of self-esteem as a phenomenological construct is inextricably linked to its measurement. If people subjectively experience themselves as competent, likable, and valued, then they necessarily have high self-esteem, regardless of their actual level of competence and likableness. Given this conceptualization, it is not surprising that self-esteem is most commonly assessed via self-report scales.

### Commonly Used Measures of Self-Esteem

The measurement of self-esteem is a long-standing issue in psychology, dating back to James's seminal writings on the self in 1890. Over the years, researchers have proposed a wide range of self-esteem measures. In addition to numerous self-report scales, there are "experience sampling" measures, pictorial and puppet measures for children, measures based on observer and peer ratings, self-ideal discrepancy measures, measures based on preferences for the letters in one's name, and reaction time measures such as the Implicit Association Test (IAT). The vast majority of researchers rely on face-valid self-report scales (i.e., scales in which what is being assessed is obvious); therefore, this section focuses on several of the most widely used self-report scales. However, measures of implicit self-esteem are increasing in popularity, so this section also reviews the most commonly used implicit measure, the IAT. This section ends by discussing the degree to which different self-esteem scales and measures are correlated with each other (i.e., convergent validity).

### Self-Report Scales

The most commonly used self-report scale is the Rosenberg Self-Esteem Scale, followed by the Coopersmith Self-Esteem Inventory, the Harter

Self-Perception Profile, and the Marsh Self-Description Questionnaire. The Rosenberg scale assesses global self-esteem. The other three measures assess global and domain-specific self-evaluations, but in some research contexts, only the global self-esteem subscales are used.

*Rosenberg Self-Esteem Scale (RSE).* In work with adults, the RSE is by far the most widely used measure of self-esteem, and it has received more psychometric analysis and empirical validation than any other self-esteem measure. The RSE is made up of 10 face-valid items, 5 positively worded and 5 negatively worded. Most researchers use a 4-, 5-, or 7-point Likert scale with the end points labeled *strongly disagree* to *strongly agree*. Several researchers have adapted or shortened the RSE. Most recently, a single-item version (SISE) was developed and validated for use when time is limited. The SISE asks the participant to rate the statement “I have high self-esteem” using a 5-point Likert scale.

*Coopersmith Self-Esteem Inventory (SEI).* The SEI was developed to assess multiple self-concept domains in children. The original SEI assessed four domains (peers, parents, school, and personal interests) and included 50 items that were rated as being unlike me or like me. Coopersmith later created a modified version based on the best 25 items. The SEI is primarily used with children, but an adult scale is also available.

*Self-Perception Profile (SPP).* The SPP was developed to assess multiple domains of self-concept and includes a separate global self-concept subscale. The original SPP was developed for children, but it has been adapted for use with adolescents, college students, and adults. Therefore, the SPP has the advantage of allowing cross-age comparisons.

The SPP presents two statements and asks the participant to choose the one that is most self-descriptive, and then rate it as *a lot like me* or *a little like me*. These responses are coded into a 4-point scale. The scale for young children (with preschool to first grade and boy and girl versions available) is administered individually in pictorial format, eliminating the need for reading skills. However, no global subscale is available for young children because it has been argued that children under 8 cannot communicate feelings of global self-worth. The other scales use the same format as the scale for young children, except pictures are not used. All scales assess multiple dimensions, but some of the dimensions vary to ensure that they are age appropriate.

*Self-Descriptive Questionnaire (SDQ).* The SDQ was developed to assess domain-specific self-evaluations across age groups and includes a separate global subscale. The SDQ is longer than most other self-concept scales and it has separate forms for children (76 5-point Likert items), for adolescents (102 6-point Likert items), and for college students and adults (136 8-point Likert items). If cross-age comparisons are desired, these scales can be adapted to use the same response format. All scales assess multiple dimensions, but some of the dimensions vary to ensure they are age appropriate.

### ***The Implicit Association Test (IAT)***

The self-report scales described above may not tap true, deep-seated feelings about the self because they are face-valid. Therefore, participants might base their answers on what they believe the scale administrator wants to hear or what they believe is most socially desirable. To address this concern, researchers have developed measures of implicit self-esteem (i.e., aspects of self-evaluation that are assumed to be automatic, overlearned, and operative outside of conscious awareness). Such measures are believed to avoid the need for direct self-evaluation that occurs when individuals are asked to complete a self-report measure of self-esteem.

One of the most commonly used measures of implicit self-esteem, the IAT, uses a computerized reaction time procedure to assess the degree to which individuals associate the self with positive versus negative concepts. The IAT self-esteem score is based on the difference between the time it takes an individual to respond to positive items linked with the self versus negative items linked with the self. A person with high implicit self-esteem will link positive items with the self faster than negative items (i.e., they have an implicit representation of the self as positive). Because the task requires the individual to respond extremely quickly, the associations assessed through this procedure are assumed to be automatic and unconscious. If the IAT is administered along with a self-report measure of self-esteem, the IAT should be administered first to avoid carryover effects.

### ***Correlations Between Measures***

Different self-report measures of self-esteem tend to be moderately to strongly correlated with each other ( $r$ s = .40 to .70). Substantially lower correlations

are found between self-esteem measures based on different assessment methods. Correlations between self and observer/informant reports of self-esteem generally range from the .20s to the .40s. Correlations between self-report scales and implicit measures of self-esteem are generally weak to nonexistent; that is, an individual's self-reported level of self-esteem has virtually no relation to measurements of his or her implicit level of self-esteem. Researchers are currently debating whether this lack of convergence reflects problems with the validity of the implicit measures or the fact that explicit and implicit self-esteem are psychologically distinct constructs and therefore should not be empirically related. Findings such as this raise a number of broader issues regarding the use of self-esteem measures in research and real-world contexts. Some of these issues are addressed in the following section.

### **Broader Issues**

#### ***Is Self-Esteem a Stable Trait or a Transient State?***

Researchers who study the correlates and consequences of self-esteem generally assume it is a stable trait that predicts future behavior. The research literature provides ample support for this claim. Although self-esteem levels can be temporarily elevated or depressed in everyday life and through laboratory manipulations, numerous longitudinal studies have documented the stability of self-esteem across years and even decades of life. Test-retest correlations for self-esteem are comparable to those found for more basic dimensions of personality, such as extraversion, conscientiousness, and neuroticism. At the same time, the stability of self-esteem is far from perfect, even after taking into account the attenuating effects of measurement error (i.e., scale unreliability). Thus, self-esteem, like more basic personality traits, continues to change throughout the life span.

#### ***Is Socially Desirable Responding a Concern?***

An important question is whether individuals with high self-esteem truly believe the highly desirable picture they paint of themselves, or if they are intentionally hiding their personality flaws and inflating their

virtues. A related question is whether they are in fact responding honestly (i.e., basing their responses on conscious self-beliefs), but lack insight into their deep-seated, unconscious feelings. These two forms of social desirability—intentional self-presentation (or impression management) and self-deception—have been examined in relation to self-esteem.

Self-esteem is generally not associated with the impression management facet of social desirability, but it is associated with self-deception. Thus, high self-esteem individuals generally do not attempt to manipulate their responses to portray themselves in a positive light to others. However, they may be prone to self-deception because they are unaware of self-doubts about their competence, attractiveness, and likableness. Whether or not this poses a problem in the measurement of self-esteem depends on one's conceptualization of self-esteem. If self-esteem is defined in terms of conscious experience, then the fact that conscious self-evaluations may not reflect unconscious feelings and beliefs does not pose a problem for the assessment of self-esteem. However, if unconscious feelings and beliefs are assumed to be central to self-esteem, then implicit measures might be more valid and useful than explicit measures.

#### ***Is Self-Esteem Distinct From Related Personality Constructs?***

Self-esteem is empirically related to several basic dimensions of personality. High self-esteem individuals tend to score high on the traits Extraversion, Conscientiousness, Agreeableness, and Openness to Experience, and low on Neuroticism. Despite this empirical overlap, self-esteem often predicts important life outcomes over and above these basic personality dimensions.

A more complex issue is the relation between self-esteem and narcissism. Measures of self-esteem and measures of narcissism tend to be moderately correlated. However, theories of narcissism suggest that this overlap is not valid, but rather reflects a tendency for narcissistic individuals to have inflated self-esteem as a way of defending against unconscious feelings of inadequacy. From this perspective, self-esteem measures are contaminated by narcissism, because narcissistic individuals attain higher scores than is warranted by their true level of self-esteem. To correct for this problem, some

researchers have conducted statistical analyses to empirically distinguish individuals whose self-esteem is inflated by narcissism from those who have genuinely high self-esteem. In many prediction contexts, the removal of narcissistic tendencies from measures of self-esteem actually increases the predictive validity of self-esteem and can even reverse the direction of self-esteem effects.

### **Assessing Self-Esteem in Young Children**

Despite some divergence of opinion, most researchers believe that self-report, pictorial, or puppet-based measures of global self-esteem are valid for children as young as age 5 or 6, and virtually all researchers believe that global self-esteem scales are valid for children age 8 and older.

### **Differences in Self-Esteem as a Function of Age, Sex, Social Class, and Ethnicity**

Self-esteem tends to be high in childhood, drops during adolescence (particularly for girls), increases gradually throughout adulthood, and then declines sharply in old age. Despite these changes in average levels, individuals tend to maintain their relative ordering: Individuals who have relatively high (or low) self-esteem at one point in time tend to have relatively high (or low) self-esteem years later. Nevertheless, this rank-order stability is somewhat lower during childhood and old age than during adulthood.

On average, men's self-esteem scores tend to be about one third of a standard deviation higher than women's self-esteem scores. This gender difference emerges during adolescence and holds across most of the life span. Socioeconomic status is very weakly related to self-esteem levels; wealthy individuals have only slightly higher self-esteem than working class individuals. In the United States, African Americans and Caucasians tend to report the highest levels of self-esteem, followed by Latinos/as and then Asian Americans.

A voluminous body of research suggests that self-report measures of self-esteem are useful tools in psychological assessment—they are reliable, valid in a wide range of populations, and predict important real-world outcomes. In short, if the goal is to discover whether individuals consciously experience positive self-regard, it may be possible, as the eminent

psychologist Gordon Allport suggested, to simply ask them.

## **SELF-HELP GROUPS**

---

Self-help groups consist of individuals who share the same problem or concern. Group members provide emotional support to one another, learn ways to cope, discover strategies for improving their condition, and help others while helping themselves. Self-help groups, also referred to as *support groups* or *mutual help groups*, are cost-free, voluntary groups that have no limit as to how long a person can attend. Self-help

groups rely on the experiential knowledge of members, as everyone has valuable contributions based on their unique experiences. Self-help groups encourage personal responsibility and self-care, with most self-help groups having one or more of the following three basic functions: (1) providing social support for members so that they can overcome life-disrupting problems through mutual support and assistance; (2) providing education about the problem or concern the group addresses, often through presentations from health and mental health professionals and materials obtained at group meetings; (3) providing advocacy for bringing about social and/or personal change to improve conditions for those who face the same issue or problem.

While the most widely recognized self-help group is Alcoholics Anonymous, there are groups available for nearly every concern and problem. Self-help groups are available for addictions; physical illness and health; parenting, family, and youth; disability; grief and bereavement; mental illness and health; emotional, physical, and sexual abuse; widowhood; divorce; and pregnancy, childbirth, and fertility concerns.

Research estimates that more than 25 million Americans have been involved in self-help groups at some point during their lives and as many as 10 million have attended a group in the previous year. As self-help groups have gained popularity, they have increasingly come to be recognized as an emerging social movement. Over the past half century, self-help groups have become a prominent component of healthcare systems across the world. Yet, because of their grassroots nature, the growth of self-help groups has primarily been through word of mouth. The growth of self-help groups can likely be attributed to a number of reasons, including greater recognition of the unique benefits self-help groups, growing acceptance and use of alternative therapies and approaches across the United States, and limited access to health and mental health professional services.

A growing body of research and literature suggests that self-help groups are an effective and efficient complement to traditional health and human services. The benefits of self-help groups are well documented in these studies. The benefits include improved patient/client outcome, greater social and emotional support, and higher levels of personal satisfaction. Additional benefits include a better understanding of the disease or concern leading to better decision making; lower unnecessary dependence on the healthcare system; and improved access to health care.

A number of reasons have been offered suggesting why self-help groups work for those who attend. These reasons include:

- *Instant identity.* Recognizing that there are others who face the same situation or problem
- *Empowerment.* Being able to meet the challenges and concerns using their own strengths and abilities
- *Mutual self-disclosure.* Sharing with one another about their experiences
- *Helper-therapy principle.* Growing stronger through the process of helping others
- *Social role models.* Noticing that others who have experienced the same situation, issue, or problem are in a better position and able to cope
- *Shared ideology.* Creating a new understanding of the situation, issue, or problem based on shared experiences

Self-help groups have increasingly come to be viewed as dynamic and complex social groups. While the 12 steps of Alcoholics Anonymous continue to be the most widely recognized model, self-help groups are growing in their diversity, with differences in their structure, mission, and focus. Many self-help groups meet in churches, hospitals, or individual members' homes, with little external support or prescribed structure. Other groups have developed into nationally recognized nonprofits with sophisticated structures and political power (e.g., National Alliance for the Mentally Ill). Similar to other community-based programs and services, most self-help groups do not simply exist without outside factors contributing to their development. Previous research has found that many self-help groups have some type of formal relationship with either national self-help organizations, local agencies, and/or professionals in their community.

### **Professional Involvement in Self-Help Groups**

Health and human service professionals are increasingly aware of and involved in assisting self-help groups. The extent of professional involvement in self-help groups ranges from groups with no involvement to those that have a professional actively involved in group meetings. Many professionals, particularly counselors, have supported the self-help group movement. The ideas and principals of self-help groups are consistent with those of counseling, including a strength-based approach, recognition of participants'

experiences, and empowering others. At the same time, the dilemma faced by counselors is the extent to which they should be involved in self-help groups, and in particular how they can support people starting self-help groups. Professional therapists, counselors, and health and human service professionals can support self-help groups in a number of ways as described below.

### ***Referrals to Self-Help Groups***

Self-help groups' primary needs are public awareness and new members. Health and human service professionals are "gatekeepers" to many individuals who could benefit from participation in a self-help group.

### ***Forming a Core Group of Leaders***

One of the most important roles a counselor can play is to encourage the development of shared leadership in new self-help groups. When someone expresses interest in starting a group, counselors might suggest finding others who would be interested in helping. Several people contributing to the development of a group creates shared responsibility for the group and clarifies its purpose. One of the tenets of self-help groups is shared leadership, which has also been found to predict successful groups. Perhaps most importantly, the organizational tasks of the group are no longer the responsibility of one individual, thus decreasing the potential of the leader's experiencing frustration and burnout.

### ***Setting Realistic Expectations***

Group founders are motivated to start groups because they want to help others and believe that self-help groups provide the type of help that is needed. Yet, starting a group also involves a number of organizational tasks. Potentially, there is incongruence between founders' expectations for starting a group and the reality. Counselors are in a position to help founders recognize that starting a group involves both help giving and receiving, as well as organizational aspects. In many cases, it takes up to 6 months for a group to form and have regular group meetings. Counselors can help founders to have more realistic expectations as the group develops.

### ***Assisting With Organizational Tasks***

Several discussions prior to group meetings can be useful to clarify hopes, purpose, and format.

Counselors' skills match nicely with helping facilitate these meetings without becoming the group leader. Regular discussions regarding the direction of the group can also be useful, as members have an opportunity to express their opinions about group topics, speakers, and structure.

A second organizational task identified by self-help group founders was finding adequate meeting locations. Counselors often are knowledgeable about accessible, cost-free meeting locations. With a limited amount of effort, counselors can suggest to founders a number of meeting locations, allowing them to decide which would fit their needs.

### ***Connecting With Groups and the Local Community***

Counselors are very knowledgeable about community resources. Self-help groups represent another resource for counselors' clients and patients. By maintaining information about self-help groups, counselors can help new groups by referring clients and patients.

Strong relationships with community organizations and professional gatekeepers can help newly developing groups receive much-needed referrals from other sources. Counselors are particularly well suited for helping group founders make these connections due to their knowledge of local social services, organizations, and professionals.

Self-help groups are a useful complement to the services of health and mental health professionals, providing participants with opportunities to learn, grow, and help others. These groups are effective in improving the outcomes of participants, especially considering that they are free.

## SELIGMAN, MARTIN E. P. (1942– )

Martin Elias Peter Seligman was born August 12, 1942, in Albany, New York. As an undergraduate, he majored in philosophy at Princeton University, and he took his Ph.D. in psychology at the University of Pennsylvania under the supervision of Richard Solomon. Except for sabbatical leaves and a brief stint teaching at Cornell University, Seligman has spent his professorial career at the University of Pennsylvania, where he is professor of psychology. He is best known for his work on learned helplessness, depression, optimism, and positive psychology.

In the 1960s and early 1970s, Seligman and fellow University of Pennsylvania graduate students discovered and investigated the phenomenon of *learned helplessness*. Animals exposed to uncontrollable aversive events later showed striking deficits in different situations; that is, they behaved helplessly. Seligman interpreted this phenomenon in cognitive terms, at the time a radical approach. He proposed that an animal that learned in one situation that its responses were independent of outcomes generalized an expectation of response-outcome independence (i.e., helplessness) to other situations. He demonstrated the same phenomenon among people, and proposed that the basic learned helplessness phenomenon might serve as a laboratory model for reactive depression.
